In a data word each position carries a label from a finite alphabet and a data value from some infinite domain. This model has been already considered in the realm of semistructured data, timed automata and extended temporal logics.

This paper shows that satisfiability for the two-variable fragment $\text{FO}_2(\sim, <, +1)$ of first-order logic with data equality test $\sim$, is decidable over finite and over infinite data words. Here, $+1$ and $<$ are the usual successor and order predicates, respectively. The satisfiability problem is shown to be at least as hard as reachability in Petri nets. Several extensions of the logic are considered, some remain decidable while some are undecidable.

Categories and Subject Descriptors: F.4.3 [Mathematical logic and formal languages]: Formal Languages

General Terms: Theory

Additional Key Words and Phrases: Data words, one equivalence relation, first-order logic, two variables, Petri net reachability

1. INTRODUCTION

When developing algorithms for property validation, it can be convenient to have decidable logics at hand, that can refer to data from some unbounded domains. Examples can be found in both program verification and database management. In this paper we reconsider a data model that was investigated both in verification (related to timed languages [Bouyer et al. 2003] and extended temporal logics [Denri et al. 2007; Denri and Lazić 2009]), as well as XML reasoning [Neven et al. 2004]. As in these papers, data values are modeled by an infinite alphabet, consisting of a finite and an infinite part. The logic can address the finite part directly, while the infinite part can only be tested for equality. As a first step, this paper considers simple models: words, both finite and infinite.

Our main result is that over word models, satisfiability is decidable for first-order logic with two-variables, extended by equality tests for data values. The problem becomes undecidable when
more variables are permitted, or when a linear order on the data values is available, or when more
 equivalence relations are available.

Following [Bouyer et al. 2003], a data word is a finite sequence of positions having each a label
over some finite alphabet together with a data value from an unbounded domain. The logic
admits the equality test \( x \sim y \), which is satisfied if both positions \( x, y \) carry the same data value.
In addition, the logic uses the linear order \(<\) and the successor relation \(+1\). It should be noted
that in \( \mathit{FO}^2 \), first-order logic with only two variables, the successor \(+1\) cannot be defined in terms
of the order \(<\). As usual, we also have a unary predicate corresponding to each letter of the finite
alphabet. A typical formula would be \( \forall x \forall y \ (x = y + 1) \rightarrow (a(x) \lor x \sim y) \), expressing that for
every two successive positions, the right position has label \( a \), or both positions have the same data value.

Perhaps surprisingly, we show that the satisfiability problem for \( \mathit{FO}^2(\sim, <, +1) \) is closely re-
lated to the well known problem of reachability in Petri nets. More precisely, we show that every
language formed by the projection onto the finite alphabet of word models satisfying an
\( \mathit{FO}^2(\sim, <, +1) \) sentence is recognized by an effectively obtained multicounter automaton, a model
whose emptiness is equivalent to Petri net reachability. We give a 2\text{EXP}\text{TIME} reduction of satisfia-
bility of \( \mathit{FO}^2(\sim, <, +1) \) sentences to emptiness of multicounter automata, the latter being decidable by
[Mayr 1984; Kosaraju 1982]. For the opposite direction we provide a \text{P}\text{TIME} reduction from
emptiness of multicounter automata to satisfiability of \( \mathit{FO}^2(\sim, <, +1) \) sentences. Since there is
no known elementary upper bound for emptiness of multicounter automata (see e.g. [Escarza
and Nielsen 1994]), the exact complexity of satisfiability for \( \mathit{FO}^2(\sim, <, +1) \) remains a challenging
question.

The decidability of \( \mathit{FO}^2(\sim, <, +1) \) immediately implies the decidability of \( \mathit{EMSO}^2(\sim, <, +1) \).
Here \( \mathit{EMSO}^2 \) stands for formulas of \( \mathit{FO}^2 \) prefixed by existential quantification over sets of word
positions. Without data values, \( \mathit{EMSO}^2(+1) \) has the same expressive power as monadic second-
order logic. In this sense, the decidability of \( \mathit{EMSO}^2(\sim, <, +1) \) can be seen as an extension of the
classical decidability result of monadic second-order logic over words. It should be noted however
that full monadic second-order logic (and even first-order logic) over data words is known to be
undecidable [Neven et al. 2004].

We also show that the satisfiability problem for \( \mathit{FO}^2(\sim, <, +1) \) remains decidable over data \( \omega \-
words. In this case we no longer recognize the string projection of definable languages, but we show that it is decidable whether an \( \mathit{FO}^2(\sim, <, +1) \) formula is satisfied in a data \( \omega \)-word whose
string projection is ultimately periodic, using again multicounter automata.

Then we show that our decision procedure works even when the logic is extended by predicates
\( \oplus 1 \) and \( +2, +3, \ldots \). Here \( \oplus 1 \) is a binary predicate, which relates two positions if they have the same
data value, but all positions between them have a different data value. The \( +k \) binary predicate
generalizes the successor predicate \(+1\) to the \( k \)-th successor.

\textit{Paper overview.} The paper is organized as follows. The main result – a decision procedure
for satisfiability of \( \mathit{FO}^2(\sim, <, +1) \) sentences – and its main proof steps are stated in Section 3.
The proof is presented in sections 4 - 6. The proof introduces the concept of data automaton
in Section 4. There are two steps in the proof: first we show in Section 5 that each language
definable in \( \mathit{FO}^2(\sim, <, +1) \) can be recognized by a data automaton; then we show in Section 6 how
emptiness for data automata can be decided using multicounter automata. In Section 7 we study
complexity issues. We show that satisfiability of \( \mathit{FO}^2(\sim, <, +1) \) is at least as hard as non-emptiness
of multicounter automata. However, we show that satisfiability for \( \mathit{FO}^4(\sim, <) \), where the successor
\(+1\) is not allowed, is \text{NExp}\text{TIME}-complete. In Section 8, we extend the main decidability result:
first by adding new predicates, then by considering \( \omega \)-words. Finally, in Section 9, we show that
the logic becomes undecidable when: a) two equivalence relations are allowed, or b) three variables
are allowed (even without the order \(<\)); or c) a linear order on data values is included. We conclude
with a discussion of the results.

\textit{Related work.} Automata on finite strings of data values (without labels) were introduced in [Shemesh
and Francez 1994; Kaminski and Francez 1994]. The automaton model used there is based on
registers for storing data values and comparing w.r.t. equality. In [Neven et al. 2004] register

ACM Transactions on Computational Logic, Vol. V, No. N, Month 20YY.
automata and pebble automata over such words were studied. Several versions of these automata (one-way/two-way, deterministic/nondeterministic/alternating) were compared. Most of the results were negative however, i.e., most models are undecidable. Register automata have also been considered by Bouyer et al. [Bouyer et al. 2003] in the realm of timed languages. However, as their automata proceed in a one-way fashion, just as the automata in [Shemesh and Francez 1994; Kaminski and Francez 1994], the expressive power is limited, e.g. one cannot test whether all data values are different. In particular the projection of a language recognized by one-way register automata onto the finite alphabet is always regular. This is not the case for the logic considered in this paper.

In [Demri et al. 2007] an extension of LTL was introduced which can manipulate data values using a freeze operator. Decidability of LTL with one freeze operator is obtained in [Demri and Lazić 2009] using a reduction to faulty Minsky machines. This fragment is incomparable in expressive power to $\text{FO}^2(\sim, <, +1)$ as it can only process the word left-to-right (in particular it cannot express the formula $\psi_{a,b}$ given in Example 1 below), but can express properties that $\text{FO}^2(\sim, <, +1)$ cannot. LTL can be extended with the past temporal operators, and a syntactic fragment of past-LTL with one freeze operator equivalent to $\text{FO}^2(\sim, <, +1)$ was given in [Demri and Lazić 2009].

Restricting first-order logic to its two-variable fragment is a classical idea when looking for decidability [Grädel and Otto 1999]. Over graphs or over arbitrary relational structures, first-order logic is undecidable, while its two-variable fragment is decidable [Mortimer 1975]. However, this result neither implies the decidability of $\text{FO}^2(\sim, <, +1)$, nor the $\text{NExpTime}$-completeness of $\text{FO}^2(\sim, <)$, since the equivalence relation $\sim$, the order $<$ and the successor relation $+1$ cannot be axiomatized with only two variables. A related result is the $\text{NExpTime}$-completeness of two-variable logics over ordered structures with arbitrary additional binary predicates [Otto 2001]. This result is not helpful for us, as our linear order is a particular one (the transitive closure of the successor relation). A recent paper generalized the result of [Mortimer 1975] in the presence of one or two equivalence relations [Kieroński and Otto 2005]. Again this does not apply to our context as we also have the order and the successor relation. However [Kieroński and Otto 2005] also showed that $\text{FO}^2$ with three equivalence relations, without any other structure, is undecidable. This implies immediately that we cannot extend the decidability result to data words with more than two data values per position. In Section 9, we show that in our framework already two equivalence relations yield undecidability.

In the context of XML reasoning we considered $\text{FO}^2(\sim, +1)$ over unranked ordered data trees in [Bojańczyk et al. 2006; Bojańczyk et al. 2009] and showed the decidability of the satisfiability question. For unranked ordered data trees, the predicate $+1$ actually stands for two successor predicates, one for the child axis and one for the next sibling axis. As data words are special cases of data trees, this implies the decidability of $\text{FO}^2(\sim, +1)$ over words. The complexity for data trees is in $3\text{NExpTime}$ but can be brought down to $2\text{NExpTime}$ when restricted to data words (or possibly even further down, the best lower bound we know is $\text{NExpTime}$). This should be contrasted with the complexity of satisfiability of $\text{FO}^2(\sim, <, +1)$, which is not known to be elementary.

On words over a finite alphabet (without data values), the $\text{FO}^2(\sim, +1)$ fragment of first-order logic is very well understood. A characterization in terms of temporal logic says that it is equivalent to LTL restricted to the unary operators $F, G, X$ and their past counterparts [Etessami et al. 2002]. The satisfiability problem for $\text{FO}^2(\sim, +1)$ is $\text{NExpTime}$-complete with an arbitrary number of atomic predicates [Etessami et al. 2002] (in the presence of $+1$ the lower bound is achieved already with one atomic predicate). Moreover, satisfiability of $\text{FO}^2(<)$ is $\text{NP}$-complete if the number of predicates is constant [Weis and Immerman 2009]. In terms of automata, $\text{FO}^2(<)$ is equivalent to partially-ordered, two-way deterministic finite automata [Schwentick et al. 2001], while in terms of algebra the logic corresponds to the semigroup variety DA [Thérien and Wilke 1998].

This paper is the journal version of [Bojańczyk et al. 2006]. New results have been included and the proofs of the old ones have been considerably modified and simplified since the conference version.
2. PRELIMINARIES

Let $\Sigma$ be a finite alphabet of labels and $D$ an infinite set of data values. A data word $w = w_1 \cdots w_n$ is a finite sequence over $\Sigma \times D$, i.e., each $w_i$ is of the form $(a_i, d_i)$ with $a_i \in \Sigma$ and $d_i \in D$. The idea is that the alphabet $\Sigma$ is accessed directly, while data values can only be tested for equality. So data words are actually words over $\Sigma$ endowed with an equivalence relation on the set of positions. Two positions are equivalent if their data values are equal. We write $\sim$ for this equivalence relation.

\[
\begin{array}{cccccccccccc}
17 & 5 & 2 & 3 & 3 & 2 & 2 & 7 & 17 & 3 & 4 & 5 & 2 & 3 & 3 & 4 & 4 & abc\,caabb\,caabb\,caabb
\end{array}
\]

Fig. 1. (a) A data string $w$ and (b) its string projection

The string $\text{str}(w) = a_1 \cdots a_n$ is called the string projection of $w$. A data word $v$ of length 19 over alphabet $\{a, b, c\}$ and with data values from $\mathbb{N}$ is shown in Figure 1 (a), its string projection is displayed in (b). A data language is a set of data words, for some $\Sigma$. For a data language $L$, we write $L(w)$ for $\{\text{str}(w) \mid w \in L\}$.

A class is a maximal set of positions in a data word with the same data value. Thus, a class is just an equivalence class of the relation $\sim$. For a class with positions $i_1 < \cdots < i_k$ the class string is $a_{i_1} \cdots a_{i_k}$.

In the example of Figure 1, $\{1, 10, 11\}$ is the class of positions carrying the value 17. Its class string is abc.

Let $\text{FO}(\sim, <, +1)$ be first-order logic with the following atomic predicates: $x \sim y$, $x < y$, $x = y + 1$, and a predicate $a(x)$ for every $a \in \Sigma$. A data word can be seen as a model for this logic, where the carrier of the model is the set of positions in the word. The interpretation of $a(x)$ is that the label in position $x$ is $a$. The order $<$ and successor $+1$ are interpreted in the usual way. Two positions satisfy $x \sim y$ if they have the same data value. We write $L(\varphi)$ for the set of data words that satisfy a sentence $\varphi$. A formula satisfied by some data word is called satisfiable. We write $\text{FO}^k$ for formulas with at most $k$ variables. Note that the examples below use 2 variables only.

**Example 1** We present here a formula $\varphi$ such that $\text{str}(L(\varphi))$ is exactly the set of words over $\{a, b\}$ that contain the same number of $a$ and $b$.

—The formula $\varphi_a$ says all $a$-positions are in different classes:

\[
\varphi_a = \forall x \forall y (x \neq y \land a(x) \land a(y)) \rightarrow x \neq y .
\]

Similarly we define $\varphi_b$.

—The formula $\psi_{a,b}$ says each class with an $a$ also contains a $b$:

\[
\psi_{a,b} = \forall x \exists y (a(x) \rightarrow (b(y) \land x \sim y)).
\]

Similarly we define $\psi_{b,a}$.

—Hence, in a data word satisfying $\varphi = \varphi_a \land \varphi_b \land \psi_{a,b} \land \psi_{b,a}$ the numbers of $a$ and $b$-labeled positions are equal.

This can be easily extended to describe data words with an equal number of $a$, $b$ and $c$, hence a language with a string projection that is not even context-free.

For a data word $w$ and a formula $\alpha$ with one free variable (which will be usually quantifier-free) we denote by $\text{Lst}_{\alpha}(w)$ the last position of $w$ in which $\alpha$ holds, if such position exists (undefined otherwise). Similarly, $\text{Fst}_{\alpha}(w)$ denotes the first position of $w$ that satisfies $\alpha$, if it exists (undefined otherwise). For example, if $\alpha$ is the formula $b(x)$ then $\text{Lst}_{\alpha}(w) = 17$ and $\text{Fst}_{\alpha}(w) = 2$. By $\text{Llst}_{\alpha}(w)$ we denote the last position of $w$ satisfying $\alpha$ that belongs to a different class than $\text{Lst}_{\alpha}(w)$, if it exists (undefined otherwise). The formula $\text{Ffst}_{\alpha}(w)$ is defined similarly, as the first position $\ldots$
satisfying $\alpha$, that belongs to a different class than $\text{Fst}_\alpha(w)$. In the example, $\text{Llst}_\alpha(w) = 13$ and $\text{Ffst}_\alpha(w) = 4$.

**Example 2** For $a \in \Sigma$, the formula $\psi_{\text{Ffst},a}(x)$ below is satisfied precisely by the position $\text{Ffst}_a(x)(w)$.

\[
\psi_{\text{Ffst},a}(x) = a(x) \land \exists y \ (y < x \land a(y) \land x \sim y) \land \\
\forall y \ (y < x \land a(y)) \rightarrow [x \sim y \land \forall x \ (x < y \land a(x)) \rightarrow x \sim y]
\]

Note how in this example the variable $x$ is reused.

3. DECIDABILITY OF $\text{FO}^2(\sim, <, +1)$

The main result of this paper is the following:

**Theorem 3** Satisfiability of $\text{FO}^2(\sim, <, +1)$ formulas over data words is decidable.

The basic idea of the proof of Theorem 3 is to compute for each formula $\varphi$ a multicounter automaton (defined in Section 6) that recognizes $\text{str}(L(\varphi))$. As an intermediate step, we use a new type of finite automaton that works over data words, called a data automaton (to be defined in Section 4). Theorem 3 follows immediately from the following three statements.

**Proposition 4** Every language definable in $\text{FO}^2(\sim, <, +1)$ is recognized by an effectively obtained data automaton.

**Proposition 5** From each data automaton a multicounter automaton recognizing the string projection of its recognized language can be computed.

**Theorem 6** [Mayr 1984; Kosaraju 1982] Emptiness of multicounter automata is decidable.

Proposition 4 is shown in Section 5, and Proposition 5 is shown in Section 6. Regarding complexity, satisfiability of an $\text{FO}^2(\sim, <, +1)$ formula is reduced in $2\text{ExpTime}$ to the emptiness of a multicounter automaton of doubly exponential size.

4. AUTOMATA OVER DATA WORDS

In this section we first recall the definition of register automata and then we introduce data automata. Both are automata that recognize data languages. We then state a result of [Björklund and Schwentick 2007] showing that data automata can simulate register automata. Both kinds of automata will be used in the proof of Theorem 3.

4.0.0.1 **Register automata.** A register automaton is a finite state machine equipped with a finite number of registers. These registers can be used to store data values from $D$. Since the two-way model is undecidable [Neven et al. 2004], we consider here only one-way register automata. When processing a word, an automaton compares the data value of the current position with values in the registers with respect to equality; based on this comparison, the current state and the label of the position, the automaton can decide on its action. This model has been introduced in [Kaminski and Francez 1994] where it was shown that emptiness is decidable. We present the definition in a way that fits with data words.

A $k$-register automaton has a finite state space $Q$ and a number $k$ of registers. Each transition of the automaton is a tuple from

\[
Q \times \Sigma \times 2^{\{1, \ldots, k\}} \times Q \times \{1, \ldots, k, \bot\}.
\]

A tuple $(p, a, E, q, i)$ is interpreted as follows: (1) the current state is $p$, (2) the label in the current position is $a$, and (3) the data value $d$ in the current position matches a register $j$ iff

\footnote{Our data automata differ from what is called data automata in [Bouyer et al. 2003], which are essentially one-way register automata.}
$j \in E$, then the automaton moves to the next position, changes the state to $q$, and stores $d$ in register $i$ unless $i = \perp$. The automaton accepts a data word if it has a run that begins in the designated initial state $q_0 \in Q$ and ends in one of the designated accepting states $F \subseteq Q$. In the initial configuration, the register values are undefined, and will not match any data values until overwritten during the run.

**Example 7** For every $k$, there is a $k$-register automaton recognizing the following property: “a position $x$ has label $a$ if and only if it has the same data value as position $x + k$”. Whenever the automaton reads an $a$ it stores in its state the data value of the current position in some register. Obviously, $k$ registers are sufficient.

4.0.0.2 *Data automata.* We now define the second automaton model for data words, data automata. This is a new model. A *data automaton* $D = (\mathcal{A}, \mathcal{B})$ consists$^2$ of

— a non-deterministic letter-to-letter word transducer $\mathcal{A}$ called *base automaton*, with input alphabet $\Sigma$ and output alphabet $\Gamma$ (letter-to-letter means that each transition reads and writes exactly one symbol), and

— a non-deterministic word automaton $\mathcal{B}$ called the *class automaton*, over input alphabet $\Gamma$.

A data word $w = w_1 \cdots w_n \in (\Sigma \times D)^*$ is accepted by $\mathcal{D}$ if there is an *accepting* run of $\mathcal{A}$ on the string projection of $w$, yielding an output string $b_1 \cdots b_n \in \Gamma^*$, such that, for each class $\{x_1, \ldots, x_k\} \subseteq \{1, \ldots, n\}$ in the data word $w$, with $x_1 < \cdots < x_k$, the class automaton $\mathcal{B}$ accepts the *output class string* $b_{x_1} \cdots b_{x_k}$.

In the above, the transducer $\mathcal{A}$ was chosen letter-to-letter so that the string $b_{x_1} \cdots b_{x_k}$ would be conveniently defined. In general, a transducer with output of varying length could be used, giving the same expressive power. On a similar note, the automaton $\mathcal{B}$ is only used to represent a regular language, and the definition could equivalently use a regular expression, or a deterministic automaton. On the other hand, non-determinism of the base automaton $\mathcal{A}$ is an essential feature, as the following example shows.

**Example 8** Let $L_\#$ be the language of data words $w$ fulfilling the following properties: (1) $\text{str}(w) \in a^*b^*$, (2) the data value of the $b$-position occurs exactly once, and each other value occurs precisely twice - once before and once after $b$, and (3) the order of data values in the first $a$-block of $w$ is different from the order of data values in the second $a$-block. A data automaton that checks (1) and (2) is easy to describe (even with a deterministic base automaton). For property (3), the base automaton guesses and marks two positions $x < y$ before $b$ and two positions $x' < y'$ after $b$, in such a way that $x, y'$ are both marked by 0 and $y, x'$ are both marked by 1. Then the class automaton checks that each class is either unmarked, or has two positions marked by 0, or two positions marked by 1.

For the sake of contradiction, let us assume now that $L_\#$ is accepted by a data automaton $D = (\mathcal{A}, \mathcal{B})$ with deterministic $\mathcal{A}$.

Let $n$ be the number of states of $\mathcal{A}$ and let $w = (a, d_1) \cdots (a, d_{n+1})b(a, d_1) \cdots (a, d_{n+1})$ with pairwise distinct data values $d_i$. Clearly, there are $i < j$ such that $\mathcal{A}$ has the same state $p$ after reading $(a, d_i) \cdots (a, d_j)$ as after reading $(a, d_j) \cdots (a, d_i)$. Let $v$ be the data word resulting from $w$ by switching (the first occurrences of) $(a, d_i)$ and $(a, d_j)$. It is easy to observe that (a) the final state assumed by $\mathcal{A}$ is the same for $v$ as for $w$ and, (b) the output class strings of $\mathcal{A}$ are the same for $v$ and for $w$. As $v \in L_\#$, $D$ has an accepting run for $v$. By (a) and (b), this run can be transformed into an accepting run for $w$, the desired contradiction.

In the lemma below, we use the term *letter projection* for a letter-to-letter morphism, that is a morphism defined as $h : \Sigma \to \Sigma'$, where $\Sigma, \Sigma'$ are alphabets.

---

$^2$It should be noted that this definition is slightly simpler than the corresponding definition in [Bojańczyk et al. 2006]. It was shown in [Björklund and Schwentick 2007] that both definitions define the same class of data languages.

ACM Transactions on Computational Logic, Vol. V, No. N, Month 20YY.
Lemma 9 Languages recognized by data automata are closed under union, intersection, and letter projection.

Proof. Closure under union and intersection is obtained using the usual product construction. Closure under letter projection is obtained using the non-determinism of the base automaton. □

Remark: Data automata are not closed under complementation. As an example, we show that the complement \( L \setminus L \# \) cannot be recognized by any data automaton. The proof is similar to Example 8. Assuming a data automaton \( D = (A, B) \) for \( L \) (possibly with non-deterministic \( A \)), let \( n \) be the number of states of \( A \), and choose \( w \) as above. Clearly, \( D \) has an accepting run on \( w \). We can construct a data word \( v \) as above, and show similarly an accepting run of \( D \) on \( v \).

The following lemma presents a family of data languages recognizable by data automata which will be used later in the proof.

Lemma 10 For any given regular language \( L \subseteq \Sigma^* \), there is a data automaton accepting all data words for which each class string belongs to \( L \).

Proof. The base automaton just copies its input and the class automaton checks membership in \( L \). □

One can also verify if some class string belongs to \( L \): for each position, the base automaton nondeterministically chooses to either output the input symbol or a special symbol \( \bot \). It accepts if it outputs at least one non-\( \bot \) symbol. The class automaton accepts the language \( L \cup \bot^* \).

We will use the following proposition, which shows that data automata are at least as powerful as register automata.

Proposition 11 [Björklund and Schwentick 2007] For every register automaton an equivalent data automaton can be computed in polynomial time.

The converse does not hold, since register automata do not capture the language “all positions have different data values”. A data automaton can easily recognize this language: the class automaton checks if every class string has length 1.

5. REDUCTION TO DATA AUTOMATA

The goal of this section is to prove Proposition 4, i.e. to transform a formula of \( \text{FO}^2(\sim, <, +1) \) into an equivalent data automaton of doubly exponential size.

The proof of Proposition 4 starts with a classical step for 2-variable first-order logic: transforming the given \( \text{FO}^2(\sim, <, +1) \) formula \( \varphi \) into an equivalent linear size formula in Scott normal form (see e.g. [Grädel and Otto 1999]). The latter is a formula

\[
\exists R_1 \cdots R_n (\forall x \forall y \chi \land \bigwedge_i \forall x \exists y \chi_i),
\]

where the \( R_i \) are unary predicates, and \( \chi \) and each \( \chi_i \) are quantifier-free \( \text{FO}^2(\sim, <, +1) \) formulas. ³

The idea behind the transformation is that each unary predicate \( R_i \) corresponds to a subformula of \( \varphi \) with one free variable, and marks the positions where the subformula holds. The conjuncts \( \chi \) and \( \chi_i \) ensure that these new predicates are consistent with each other.

Since data automata are closed under letter projection and intersection, it suffices to construct a data automaton for each of the formulas \( \forall x \forall y \chi \) and \( \forall x \exists y \chi_i \). This is done in Lemmas 12 and 13 below. Note that the vocabularies (alphabets) of these formulas are larger than the one of the original formula \( \varphi \), since they include the new unary predicates \( R_1, \ldots, R_n \).

Before describing these automata, however, we would like to clarify how words are represented. The signature of the logic uses unary predicates for labels, while automata work with a finite input

³It should be noted that the name Scott Normal Form usually refers to the inner first-order part. This inner formula is in general only equivalent with respect to satisfiability to the original formula.
alphabet. Technically, a letter of the input alphabet of the automaton is a bit vector, telling which predicates hold in a given position. This will be important for the estimation of the automaton’s size: given a unary predicate \( P \), there are exponentially many letters corresponding to the cases where \( P \) is true. Thus, in order to test whether \( P \) holds or not, the automaton needs exponentially many distinct transitions.

In our constructions, we will often use some particular data automata, which we describe next.

The first data automaton checks that a predicate \( S_{+1} \) marks exactly those positions \( x \) that have the same data value as their successor \( x + 1 \). From Example 7, we know that this check can be done by a register automaton. By Proposition 11, the register automaton can be transformed into a data automaton, which we denote as \( D_+ \). Predicate \( S_{+1} \) will be used in the two technical lemmas 12, 13 below, when doing a case analysis over the mutual relationship between two positions \( x, y \).

In these lemmas we guess predicate \( S_{+1} \) and check it using \( D_+ \). If the guess is correct, i.e. if \( D_+ \) accepts, then \( S_{+1} \) tells us whether neighboring positions are data equivalent.

A second kind of data automaton will be used for distinguishing non-deterministically a fixed number \( k \) of classes. The base automaton uses the output alphabet \( \Gamma_k = \{ \bot \} \cup \{ \{1, \ldots, k\} \times \{0, 1\} \} \). For each position \( i \), it guesses an output symbol \( b_i \in \Gamma_k \). It makes sure that for each \( j \in \{1, \ldots, k\} \), the symbol \((j, 1)\) is chosen at most once. The class automaton accepts a word if it is either in \( \bot^* \), or in \((j,1)(j,0)^* \) for some \( j \). Therefore, for each class, either the output symbol \( \bot \) is chosen for all positions, or the first output symbol is \((j,1)\) and all others are \((j,0)\), for some \( j \). As each \((j,1)\) is used at most once, the number \( j \) uniquely identifies a class. Thus, the class automaton “knows”, for each position, to which of the \( k \) classes it belongs (if any). Note that this automaton is not useful on its own, but will be used in conjunction with some other automaton, which will be verifying properties of the classes we guess.

In the following, a type is a conjunction of unary predicates or their negations. These unary predicates are either \( a \in \Sigma \), or additional predicates like the \( R_i \) that were introduced by the transformation into Scott normal form (some more such predicates will be introduced below).

Note that a type need not use all predicates of the signature.

**Lemma 12** For each FO\(^2(\sim, <, +1)\) formula \( \varphi = \forall x \exists y \chi \), with \( \chi \) quantifier-free, an equivalent data automaton of doubly exponential size can be constructed.

**Proof.** It is straightforward to first bring \( \chi \) into CNF, and then to rewrite \( \varphi \) as conjunction of exponentially many formulas of the following form:

\[
\psi = \forall x \exists y \left( (\alpha(x) \land \beta(y) \land \delta(x, y)) \rightarrow \gamma(x, y) \right)
\]

where \( \alpha \) and \( \beta \) denote types, \( \delta(x, y) \) is either \( x \sim y \) or \( x \not\sim y \), and \( \gamma(x, y) \) is a disjunction of atomic and negated atomic formulas that use only the order predicates \( < \) and \(+1\). It suffices now to describe a data automaton for each such formula \( \psi \). For each such formula, we will give an automaton with \( O(1) \) many states. Thus, it suffices to take the intersection of all these automata, for the exponentially many conjuncts. This results in an automaton of doubly exponential size.

The proof is a case analysis on the (small number of) possible kinds of \( \delta \) and \( \gamma \). By \( w \) we will refer to the input data word.

We start with the simpler case where \( \delta(x, y) = x \sim y \). The formula \( \psi \) requires for every \( \alpha \)-position \( x \) and \( \beta \)-position \( y \) belonging to the same class, that \( x, y \) are ordered according to \( \gamma \). Since \( \gamma \) may use the successor relation, the base automaton guesses the predicate \( S_{+1} \). The correctness of the guess is ensured by running the data automaton \( D_+ \) (cf. beginning of the section) in parallel. When \( S_{+1} \) is guessed correctly, the formula \( \psi \) amounts to a regular property that must be satisfied by each class. Using the data automaton of Lemma 10, we obtain a data automaton for \( \psi \).

We now turn to the case where \( \delta(x, y) = x \not\sim y \). Here we need to analyse the possible \( \gamma(x, y) \).

As in this case we have \( x \neq y \), it is enough to consider the following cases:

\[
\text{false, } \ x < y, \ x = y + 1, \ x \neq y + 1, \ x \leq y + 1, \ y = x + 1 \lor x = y + 1
\]

(or symmetrically, with \( x \) and \( y \) interchanged).
\[ \neg \gamma(x, y) = \text{false} \] means that \( w \) cannot have an \( \alpha \)- and a \( \beta \)-position in different classes. In particular, there can be at most one class containing \( \alpha \), and this class must contain all \( \beta \) in the word. (Or there are no \( \beta \), but this can be checked by the base automaton alone.) Using the second technique explained at the beginning of the section, a data automaton guesses (at most) one class, and checks that there are no \( \alpha \) and \( \beta \) outside this class.

\[ \neg \gamma(x, y) = (x < y) \]. Recall the notations \( \text{Lst} \) and \( \text{Llst} \) introduced in Section 2. Formula \( \psi \) holds if and only if (a) there is no \( \beta \) up to position \( \text{Llst}_\alpha(w) \); and (b) the \( \beta \)-positions between \( \text{Lst}_\alpha(w) + 1 \) and \( \text{Lst}_\alpha(w) \) are in the same class as \( \text{Lst}_\alpha(w) \). The case where \( \gamma(x, y) = x \leq y + 1 \) is handled similarly.

Thus, the base automaton simply guesses whether \( w \) has 0, 1 or more classes containing \( \alpha \) and marks the classes containing \( \text{Lst}_\alpha(w) \) and \( \text{Llst}_\alpha(w) \) (if defined). It then checks that (a) and (b) hold.

\[ \neg \gamma(x, y) = (x = y + 1) \] implies in particular that there are at most two classes with \( \alpha \) or \( \beta \). This is dealt with by marking the class(es), checking that \( \alpha \) and \( \beta \) do not occur outside, and verifying the distance condition with the base automaton. Likewise, \( y = x + 1 \lor x = y + 1 \) implies that there are at most three classes with \( \alpha \) and \( \beta \), and this case can be handled analogously.

\[ \neg \gamma(x, y) = (x \neq y + 1) \] is handled directly by the base automaton, after guessing (and checking in parallel) the predicate \( S_{+1} \).

\[ \quad \Box \]

**Lemma 13** For each \( \text{FO}^2(\sim, <, +1) \) formula \( \varphi = \forall x \exists y \chi \), with \( \chi \) quantifier-free, an equivalent data automaton of doubly exponential size can be constructed.

**Proof.** First, \( \chi \) can be written in disjunctive normal form:

\[
\bigvee_i \left( \alpha_i(x) \land \beta_i(y) \land \delta_i(x, y) \land \epsilon_i(x, y) \right),
\]

where \( \alpha_i, \beta_i \) are types, \( \delta_i \) is either \( x \sim y \) or \( x \not\sim y \), and \( \epsilon_i \) is one of \( x + 1 < y \), \( x + 1 = y \), \( x = y \), \( x = y + 1 \) or \( x > y + 1 \). We will first eliminate the disjunction. To this end, we add for each disjunct above a new unary predicate \( S_i \) with the intended meaning that if \( S_i \) holds at a position \( x \) with \( \alpha_i \), then there is a \( y \) such that \( \beta_i(y) \land \delta_i(x, y) \land \epsilon_i(x, y) \) holds. Formally, we rewrite each \( \forall x \exists y \chi \) as:

\[
\exists S_1 \exists S_2 \cdots (\forall x \bigvee_i S_i(x)) \land \bigvee_i \forall x \exists y \left( S_i(x) \rightarrow (\alpha_i(x) \land \beta_i(y) \land \delta_i(x, y) \land \epsilon_i(x, y)) \right).
\]

The subformula \( \forall x \left( \bigvee_i S_i(x) \right) \) ensures that for each \( x \), one of the disjuncts holds. It can be rewritten equivalently as \( \forall x \exists y \left( \bigwedge_i \neg S_i(x) \rightarrow \text{false} \right) \).

It remains to show that we can construct a data automaton for any formula \( \psi \) of type:

\[
\forall x \exists y \left( \alpha(x) \rightarrow (\beta(y) \land \delta(x, y) \land \epsilon(x, y)) \right).
\]

For each such formula, we will give an automaton with \( O(1) \) states. We then need to take an intersection of all these automata, for the exponentially many \( i \). This gives the doubly exponential size from the statement of the lemma.

The case where \( \delta(x, y) = x \sim y \) is treated as in Lemma 12, by guessing \( S_{+1} \) and checking a regular condition on each class. As in Lemma 12, \( S_{+1} \) is needed when \( \epsilon \) uses the successor relation.

We now consider the case when \( \delta(x, y) = x \not\sim y \). Note that this implies again that \( x \neq y \). We denote as before by \( w \) the input data word.

Assume first that \( \epsilon(x, y) = x + 1 < y \) or \( x > y + 1 \). We describe the case of \( x + 1 < y \), the other one is analogous. In this case, \( \psi \) expresses that each \( \alpha \)-position of a data word \( w \) needs a \( \beta \)-position in a different class to its right, but not as its right neighbor. First there are two special cases: if \( w \) contains no \( \beta \), then it contains no \( \alpha \) either; if all \( \beta \) are in the same class (i.e., \( \text{Lst}_\beta(w) \) is undefined), then all \( \alpha \) are outside this class and before \( \text{Lst}_\beta - 1 \). We can use in the latter case the data automaton that marks the class with \( \beta \) and let the base automaton check the previous
We would like to note that the converse of Proposition 4 does not hold, i.e. not every data automaton can be transformed into a formula. There are two reasons for this. First, a data automaton can verify arbitrary regular properties of classes, which cannot be done with first-order logic. For instance, no FO\(^2(\sim, <, +1)\) formula captures the language: “each class is of even cardinality”. This problem can be solved by adding a prefix of monadic second-order existential quantification. Formally speaking, we consider then formulas of the logic EMSO\(^2(\sim, <, +1)\). Recall that the latter is the extension of FO\(^2(\sim, <, +1)\) by existential second-order quantification over monadic predicates in front of FO\(^2(\sim, <, +1)\) formulas. Note also that as far as satisfiability is concerned FO\(^2(\sim, <, +1)\) and EMSO\(^2(\sim, <, +1)\) are equivalent. However, even with EMSO\(^2(\sim, <, +1)\), it is difficult to write a formula that describes accepting runs of a data automaton. The problem is that describing runs of the class automaton requires comparing successive positions in the same class, which need not be successive positions in the word. That is why we consider a new predicate \(\oplus\), called the class successor, which is true for two successive positions in the same class of the data word. The following result can be shown by extending the proof of Proposition 4 in a straightforward way to include EMSO\(^2(\sim, +1, \oplus)\):

**Proposition 14** Data automata and EMSO\(^2(\sim, +1, \oplus)\) have the same expressive power, and the translations are effective. In particular, satisfiability of EMSO\(^2(\sim, +1, \oplus)\) formulas over data words is decidable.

**Proof.** It is easy to extend the proof of Proposition 4 to the logic EMSO\(^2(\sim, +1, \oplus)\). The other direction follows the same lines as the classical simulation of word automata by monadic second-order logic. □

Another normal form is obtained by using the same ideas as in the proof of Proposition 4. Each formula of EMSO\(^2(\sim, <, +1)\) is equivalent to one where the FO part is a Boolean combination of formulas of the form (where \(\alpha\) and \(\beta\) are types):

(a) A formula that does not use \(\sim\) (i.e., an FO\(^2(<, +1)\) formula).

(b) Each class contains at most one occurrence of \(\alpha\).

(c) In each class, all occurrences of \(\alpha\) are located strictly before all occurrences of \(\beta\).

(d) In each class with at least one occurrence of \(\alpha\), there must be a \(\beta\), too.

(e) If \(x\) is not in the same class as \(x + 1\), then it is of type \(\alpha\).

6. FROM DATA TO COUNTERS

In this section we complete the proof of Theorem 3 by showing Proposition 5. We first introduce multicontour automata. A multicontour automaton is a finite, non-deterministic automaton extended by a number \(n\) of counters. It can be described as a tuple \((Q, \Sigma, n, \delta, q_f, F)\). The set of states \(Q\), the input alphabet \(\Sigma\), the initial state \(q_f \in Q\) and final states \(F \subseteq Q\) are as in a usual finite automaton. The transition relation \(\delta\) is a subset of

\[Q \times (\Sigma \cup \{\epsilon\}) \times \{\text{inc}(i), \text{dec}(i) \mid 1 \leq i \leq n\} \times Q.\]

In each step, the automaton can change its state and modify the counters, by incrementing or decrementing them, according to the current state and the current letter on the input (which can be \(\epsilon\)). Whenever it tries to decrement a counter of value zero the computation stops and rejects.

A configuration of a multicontour automaton is a tuple \((q, (c_i)_{i \leq n})\), where \(q \in Q\) is the current state and \(c_i \in \mathbb{N}\) is the value of the counter \(i\). A transition \((p, \epsilon, \text{inc}(i), q) \in \delta\) can be applied if
the current state is \( p \). For \( a \in \Sigma \), a transition \((p, a, \text{inc}(i), q) \in \delta \) can be applied if furthermore the current letter is \( a \). In the successor configuration, the state is \( q \), while each counter value is the same as before, except for counter \( i \), which now has value \( c_i + 1 \). Similarly, a transition \((p, a, \text{dec}(i), q) \in \delta \) with \( a \in \Sigma \cup \{\epsilon\} \) can be applied if the current state is \( p \), the current letter is \( a \), if \( a \in \Sigma \), and \( c_i \neq 0 \). In the successor configuration, all counter values are unchanged, except for counter \( i \), which now has value \( c_i - 1 \). A run over a word \( w \) is a sequence of configurations that is consistent with the transition relation \( \delta \).

A run is an accepting run if it starts in the state \( q_1 \) with all counters equal to zero and ends in a configuration where all counters are zero and the state is final.

The key idea in the reduction from data automata to multicycle automata, is that acceptance of data automata can be expressed using shuffles of regular languages. A word \( v \in \Sigma^* \) is a shuffle of \( n \) words \( u_1, \ldots, u_n \in \Sigma^* \) if its positions can be colored with \( n \) colors such that for every color \( i \), the subword corresponding to color \( i \) is \( u_i \). For a language \( L \subseteq \Sigma^* \), we write \( \text{Shuffle}(L) \) for the set of words \( v \in \Sigma^* \) such that for some \( n \in \mathbb{N} \) and some \( u_1, \ldots, u_n \in L \), the word \( v \) is a shuffle of \( u_1, \ldots, u_n \).

The link between shuffle languages and multicycle automata is given by the following result:

**Proposition 15** [Gischer 1981, Lemma (IV.6)] If \( L \subseteq \Sigma^* \) is regular then \( \text{Shuffle}(L) \) is recognized by a multicycle automaton of size bounded by the size of an NFA recognizing \( L \).

We are now ready to prove Proposition 5, completing the proof of Theorem 3.

**Proposition 5** From each data automaton \( \mathcal{D} \) one can compute in quadratic time a multicycle automaton recognizing the string projection of the language recognized by \( \mathcal{D} \).

**Proof.** Fix a data automaton \( \mathcal{D} = (\mathcal{A}, \mathcal{B}) \) and consider a word \( v \in \Sigma^* \) that belongs to the string projection \( \text{str}(L(\mathcal{D})) \). Then there exists a data word \( w \) with \( v = \text{str}(w) \) and an accepting run of the base automaton \( \mathcal{A} \) on \( v \) with output \( v' \), such that for each class \( c \) in \( w \), the substring of \( v' \) corresponding to \( c \) is accepted by the class automaton \( \mathcal{B} \). If \( L \) is the language of \( \mathcal{B} \), then this implies \( v' \) belongs to \( \text{Shuffle}(L) \).

Conversely, let \( v \in \Sigma^* \) such that on input \( v \), the base automaton \( \mathcal{A} \) outputs a word \( v' \) that belongs to \( \text{Shuffle}(L) \). Then, by the definition of the shuffle operator, there are some \( n \) and words \( u_1, \ldots, u_n \in L \) such that \( v' \) is a shuffle of \( u_1, \ldots, u_n \). Let \( l \) be a coloring of \( v' \) witnessing the fact that \( v' \) is a shuffle of \( u_1, \ldots, u_n \). Let \( w \) be the data word formed from \( v \) by assigning to each position \( w \) a data value determined uniquely by the coloring \( l \). By definition, \( w \) is accepted by \( \mathcal{D} \) and hence \( v \in \text{str}(L(\mathcal{D})) \).

Hence \( \text{str}(L(\mathcal{D})) \) is the set of words \( v \) such that some output of \( \mathcal{A} \) on \( v \) belongs to \( \text{Shuffle}(L) \).

By Proposition 15, \( \text{Shuffle}(L) \) is recognized by a multicycle automaton \( \mathcal{M} \) of the same size as \( \mathcal{B} \). We can now compose the base automaton \( \mathcal{A} \) and this automaton \( \mathcal{M} \) into a multicycle automaton that recognizes the string projection of \( L(\mathcal{D}) \). The idea is to store in each state of the new multicycle automaton a state of \( \mathcal{M} \) and a state of \( \mathcal{A} \). Thus the automaton can simulate in parallel \( \mathcal{A} \) and \( \mathcal{M} \), using non-determinism to guess the output of \( \mathcal{A} \).

7. **Complexity Results**

The proof of Theorem 3 does not yield an immediate upper bound on the complexity of satisfiability of \( \text{FO}^2(\sim, <, +1) \). From the bounds given in Lemmas 12, 13 and Proposition 5, we can only conclude that the problem can be reduced in doubly-exponential time to the emptiness of multicycle automata. For the latter problem, no elementary upper bound is known.

In this section, we first show that satisfiability of \( \text{FO}^2(\sim, <, +1) \) has about the same complexity as emptiness of multicycle automata, thus destroying the hope for efficient algorithms. We then initiate the search for more tractable logics by considering the fragments of \( \text{FO}^2(\sim, <, +1) \) obtained by dropping \(+1\) or \(<\), respectively. It will turn out that satisfiability for \( \text{FO}^2(\sim, <) \) is \( \text{NExpTime-complete} \). For \( \text{FO}^2(\sim, +1) \) we can currently only give a doubly-exponential upper bound following from our results in [Bojańczyk et al. 2006].
We first turn to the lower bound for $\text{FO}^2(\sim, <, +1)$. We show that satisfiability for $\text{FO}^2(\sim, <, +1)$ is at least as hard as non-emptiness of multicounter automata. The best lower bound known for the latter problem is $\text{ExpSpace}$ [Lipton 1976] and no elementary, or even primitive recursive, upper bound is known.

**Theorem 16** Emptiness of multicounter automata can be reduced in polynomial time to the satisfiability problem of $\text{FO}^2(\sim, <, +1)$.

**Proof.** Given a multicounter automaton $A$, we construct an $\text{FO}^2(\sim, <, +1)$ formula whose models are the encodings of accepting runs of the automaton. In particular, the formula is satisfiable if and only if the automaton accepts a nonempty language. As far as emptiness is concerned, we may assume that the automaton $A$ has a one letter input alphabet, so we omit the input letters from the transitions.

Let $Q$ be the set of states, $n$ the number of counters, and $\delta$ the transition relation of $A$. We define the alphabet $\Sigma$ as $Q \cup \{D_1, I_1, \ldots, D_n, I_n\}$. A transition $(p, \text{inc}(k), q) \in \delta$ is encoded by the word $pD_kq$, and a transition $(p, \text{dec}(k), q) \in \delta$ is encoded by $pD_kq$. A run $\rho$ of $A$ is encoded by a data word $w_\rho$ such that the string projection of $w_\rho$ is the sequence of encodings of transition steps of $\rho$ and the data values of $w_\rho$ are constrained in order to check the evolution of the counters along the run and enforce the validity of the run $\rho$ in $\text{FO}^2(\sim, <, +1)$ as explained below.

The $\text{FO}^2(\sim, <, +1)$ formula we construct from $A$ needs to enforce that: (i) the sequence of encoding transition steps is consistent with $\delta$, (ii) the counters never drop below zero and, (iii) they are empty at the end of the computation.

It is easy to enforce (i) by a formula of $\text{FO}^2(\sim, <, +1)$ of polynomial size: only the successor relation is needed here. For (ii) and (iii) we use data values to match each decrement with exactly one previous increment of the same counter and vice-versa. To do this, we constrain the data values in the following way: (1) positions labeled by the symbols $I_1, \ldots, I_n$ have pairwise distinct data values, (2) positions labeled by the symbols $D_1, \ldots, D_n$ have pairwise distinct data values, (3) each position labeled by some $D_k$ has the same data value as a position labeled by some $I_k$ to the left, and (4) each position labeled by some $I_k$ has the same data value as a position labeled by some $D_k$ to the right. The conditions (1)-(4) can easily be defined in $\text{FO}^2(\sim, <, +1)$ by a formula of polynomial size.

From any run $\rho$ satisfying (ii) and (iii) one can easily set up the data values of $w_\rho$ such that (1)-(4) hold by matching the decrement with its corresponding increment. Conversely, assume $w$ satisfies (i) and (1-4). By (i) the word $w$ represents a run $\rho$ of the automaton. The conditions (1-4) induce a bijection between $I_k$ and $D_k$ positions, such that any prefix of the word $w$ contains at least as many $I_k$ as $D_k$ positions. Thus the corresponding run $\rho$ satisfies (ii) and (iii).

Hence $A$ has an accepting run if and only if the conjunction of the formulas above is satisfiable. $\square$

Now we turn to the logic $\text{FO}^2(\sim, <)$, where the successor relation is not allowed. Removing the successor notably improves the complexity of satisfiability, making it $\text{NExpTime}$-complete.

The following result should be compared with results of [Etessami et al. 2002], which show that satisfiability is $\text{NExpTime}$-complete for $\text{FO}^2(<)$ over word models. In the latter logic, there is no $\sim$ relation to compare data values, so the word positions only have labels, and no data values. The upper bound we give in Theorem 17 strengthens the results from [Etessami et al. 2002] by showing that a $\text{NExpTime}$ decision procedure works even if data values are introduced in the logic. Our lower bound is slightly different from the one in [Etessami et al. 2002], since in the presence of data we don’t need to use any unary predicates, while the lower bound in [Etessami et al. 2002] needs arbitrarily many unary predicates. In other words, we trade data values for predicates. This tradeoff is necessary: satisfiability of $\text{FO}^2(<)$ is $\text{NP}$-complete if the number of predicates is fixed [Weis and Immerman 2009].

**Theorem 17** Satisfiability of $\text{FO}^2(\sim, <)$ formulas over data words is $\text{NExpTime}$-complete. The lower bound holds even for formulas without unary predicates.

ACM Transactions on Computational Logic, Vol. V, No. N, Month 20YY.
We first show the lower bound:

**Lemma 18** Satisfiability for \( \text{FO}^2(\sim, <) \) formulas without unary predicates is \( \text{NEXP-Time} \)-hard.

**Proof.** The reduction is from the *origin-constrained tiling problem* [Fürer 1984]. The input to this problem is given as \((T, H, V, t)\), where \(T\) is a finite set of tiles \(|T| = k\), the sets \(H, V \subseteq T \times T\) are horizontal and vertical matching relations, and \(t \in T\) is a starting tile. The question is whether there exists a tiling of the square \(2^n \times 2^n\) with the tile \(t\) in the upper left corner.

Given an instance of the tiling problem \((T, H, V, t)\), we build an \( \text{FO}^2(\sim, <) \) formula whose models are encodings of the solutions of the tiling problem. In particular, the formula has a model if and only if the tiling problem has a solution.

Let us describe the encoding of tilings by data words. Let \( T = \{t_1, \ldots, t_k\} \) and \( \pi \) be a mapping from the square \(2^n \times 2^n\) to \(T\). We encode each position \((i, j)\), \(0 \leq i, j < 2^n\), of the square with a distinct data value. This will be done by considering the binary representations of \(i\) and \(j\), respectively. An encoding of \( \pi \) is a data word where the leftmost data value appears exactly \(2n + k\) times. Every data value, except the leftmost one, will be used to encode a position \((i, j)\) in the square. By abuse of language we speak about the square position (and its horizontal/vertical coordinate) associated with a data value different from the leftmost one. The encoding is interpreted as follows:

— The blocks \( u_1 \cdots u_n \) encode the horizontal coordinates of square positions: the \( \ell \)-th bit of the horizontal coordinate \(i\) of a data value is 1 if and only if the value appears in the block \(u_\ell\). In particular, the data values associated with the first column \((i = 0)\) do not appear in any of these blocks.

— Similarly, the blocks \( v_1 \cdots v_n \) encode the vertical coordinates of square positions.

— The blocks \( w_1 \cdots w_k \) encode the labels assigned by the mapping \( \pi \). If \( \pi(i, j) = t_l\), then the data value corresponding to \((i, j)\) appears in the block \(w_m\) if and only if \(l = m\).

**Example:** Consider \( T = \{t_1, t_2, t_3\} \) and a tiling where \( t_1 \) labels positions \((0, 0)\) and \((1, 1)\), \( t_2 \) labels \((0, 1)\), and \( t_3 \) labels \((1, 0)\). One possible coding of this mapping is presented below. The data values 1, 2, 3, 4 correspond to positions with coordinates \((0, 0)\), \((1, 0)\), \((0, 1)\) and \((1, 1)\). The leftmost data value 0 is used to decide the word into blocks.

\[
\begin{array}{ccc|ccc|ccc}
& & & & u_1 & & & & u_2 & & & & u_3 \\
0 & 2 & 4 & 0 & 3 & 4 & 0 & 1 & 4 & 0 & 3 & 0 & 2
\end{array}
\]

A mapping can have several codings, e.g. by swapping or duplicating non-0 positions inside a block.

We now describe an \( \text{FO}^2(\sim, <) \) formula that tests if a data word encodes a solution of the tiling problem. The formula is the conjunction of the following properties:

1. The leftmost data value appears \(2n + k\) times.
2. No two (non-leftmost) data values appear exactly in the same blocks \( u_1 \cdots u_n \) and \( v_1 \cdots v_n \). Every (non-leftmost) data value appears in exactly one block from \( w_1 \cdots w_k \).
3. Each position of the square is associated with a data value. The constraints \( H \) and \( V \), as well as the origin constraint \( t \), are respected.

By induction on \( p \leq 2n + k\), we define a formula \( \psi_p(x) \) of polynomial size, which says that to the left of \( x \), there are exactly \( p \) occurrences of the leftmost data value. Using this formula, we can express the first property.

We now proceed to express the two remaining properties. Let \( \alpha(x) \) be the formula saying that \( x \) has a leftmost data value. The formula \( \beta_p(x) = \exists y(y \sim x \land \psi_p(y)) \) says that the data value of
position \( x \) also occurs in the \( p \)-th block. The first clause in property 2 is written as follows:

\[
\forall x \forall y \left( (x \neq y \land \neg \alpha(x) \land \neg \alpha(y)) \rightarrow \bigvee_{1 \leq p \leq 2n} \beta_p(x) \neq \beta_p(y) \right)
\]

The second clause is written similarly. Property 3 is enforced by using standard binary arithmetics on coordinates. The following formula says that the positions of the squares corresponding to the data values of \( x \) and \( y \) are in consecutive rows. Here we take the convention that the least significant bit is the rightmost one. Thus there is some \( 1 \leq p \leq n \) such that the binary representation of these two consecutive rows is respectively \( b_1 \cdots b_{p-1} 01 \cdots 1 \) and \( b_1 \cdots b_{p-1} 10 \cdots 0 \).

\[
\bigvee_{1 \leq p \leq n} \left( \neg \beta_p(x) \land \beta_p(y) \land \bigwedge_{1 \leq r < p} \beta_r(x) \leftrightarrow \beta_r(y) \land \bigwedge_{p < r \leq n} \beta_r(x) \land \neg \beta_r(y) \right)
\]

A similar formula talks about columns. Using such formulas we can enforce the existence of all the positions of the square and the consistency of the labels in neighboring positions of the tiling.

We now show the upper bound:

**Lemma 19** Satisfiability of \( \text{FO}^2(\sim, <) \) formulas is in \( \text{NExpTime} \).

**Proof.** We give a polynomial-time reduction from satisfiability of \( \text{FO}^2(\sim, <) \) to satisfiability of \( \text{FO}^2(\sim) \), and then we apply [Etessami et al. 2002], which shows that satisfiability of \( \text{FO}^2(\sim) \) is in \( \text{NExpTime} \).

As in the proof for \( \text{FO}^2(\sim, <, +1) \), we show that satisfiability of an \( \text{FO}^2(\sim, <) \) formula can be reduced to satisfiability of a formula in Scott normal form, a step that is performed in linear time. The Scott normal form formula is of the form

\[
\forall x \forall y \chi(x, y) \land \bigwedge_i \forall x \exists y \chi_i(x, y),
\]

where \( \chi \) and each \( \chi_i \) are quantifier-free and use only the order \( < \), the data equivalence relation \( \sim \) and unary predicates. Note that the new formula uses some new unary predicates, but its size—and therefore also the number of new predicates—is linear in the size of the original formula.

We now show that if a formula in Scott normal form is satisfiable, then it has a model with at most \( 2^n \cdot 2 \cdot 2^n \) classes, where \( n \) is the number of unary predicates in the formula. Since we can use \( n + 2 \) new unary predicates for encoding these classes, we obtain a polynomial-time reduction to satisfiability of \( \text{FO}^2(\sim) \), and thus the \( \text{NExpTime} \) upper bound follows as satisfiability of \( \text{FO}^2(\sim) \) is in \( \text{NExpTime} \) [Etessami et al. 2002].

Given a model \( w \) of the formula in Scott normal form, we build a new model \( w' \) by removing all positions except those from some distinguished classes. Let \( \alpha \) be a complete type, i.e., a truth assignment for all unary predicates. The new data word \( w' \) is built from \( w \) by keeping (if they exist), for each complete type \( \alpha \), the classes of positions \( \text{Fst}_\alpha(w) \), \( \text{Fst}_\alpha(w) \), \( \text{Lst}_\alpha(w) \), \( \text{Lst}_\alpha(w) \) (as defined in Section 2). All other classes are removed. Since there are \( 2^n \) possible complete types, the new data word \( w' \) contains at most \( 4 \cdot 2^{2n} \) classes.

We now show that the data word \( w' \) is still a model of the formula. The \( \forall x \forall y \chi(x, y) \) subformula holds in \( w' \), since \( w' \) is a substructure of \( w \). For the \( \forall x \exists y \) part, we show that the classes that we keep in \( w' \) suffice for satisfiability. In the data word \( w' \), every position \( x \) needs a witness \( y \) such that \( \chi_i(x, y) \) holds. Consider a position \( x \) in \( w' \) and a corresponding witness \( y \) in \( w \) for a formula \( \chi_i \). If \( y \) is in the class of \( x \), then \( y \) belongs to \( w' \), so it is also a witness of \( x \) in \( w' \). Assume now that \( y \) is not in the class of \( x \) and that it has the complete type \( \alpha \). Since \( \text{Lst}_\alpha(w) \) and \( \text{Lst}_\alpha(w) \) are in different classes (and same for \( \text{Fst}_\alpha(w) \) and \( \text{Fst}_\alpha(w) \)), one of the positions \( \text{Lst}_\alpha(w) \), \( \text{Lst}_\alpha(w) \), \( \text{Fst}_\alpha(w) \) or \( \text{Fst}_\alpha(w) \) is also a witness of \( x \) in \( w' \). For instance, if \( x < y \) then either \( x \) has the same value as \( \text{Lst}_\alpha(w) \) so we have the witness \( \text{Lst}_\alpha(w) \), or they have different values, so \( \text{Lst}_\alpha(w) \) is a witness. This shows that \( x \) has a witness in \( w' \), too.

\[\Box\]
8. DECIDABLE EXTENSIONS

8.1 More successors

It is often useful to talk about patterns in a string, which concern several consecutive positions and their mutual relationships. For instance, we might like to say that there are two positions \(x\) and \(y\) in the same class such that the substring between \(x\) and \(y\) is \(abc\). To express such properties, it would be convenient to add to the signature relations like \(\preceq\) and \(\equiv\) and their mutual relationships. For instance, we might like to say that there are two positions \(x\) and \(y\) in the same class such that the substring between \(x\) and \(y\) is \(abc\).

We denote by \(FO^2(\preceq,\prec,+\omega)\) the logic extending \(FO^2(\preceq,\prec,+\omega)\) with all predicates \(+k\). Of course any given formula of this logic uses only a finite number of predicates \(+k\), but the satisfiability algorithm must be prepared for arbitrarily large values. In this section, we show that this extension is still decidable, by adapting the proof for \(FO^2(\preceq,\prec,+1)\).

**Theorem 20** Satisfiability of \(FO^2(\preceq,\prec,+\omega)\) formulas over data words is decidable.

**Proof.** The proof follows the same lines as the proof of Theorem 3, thus we mention here only the differences.

First, we make now use of predicates \(S_{+j}\), with \(1 \leq j \leq k\). Predicate \(S_{+j}\) holds at position \(x\) iff \(x \preceq (x+j)\). As for \(S_{+1}\), we can construct a data automaton that guesses and verifies \(S_{+j}\).

Let \(\varphi\) be a formula of \(FO^2(\preceq,\prec,+\omega)\). This formula uses a finite number of successor relations \(+1, \ldots, +k\). We transform it first into Scott normal form, as in the \(FO^2(\preceq,\prec,+1)\) case. We need then to argue that Lemmas 12 and 13 still go through, using \(S_{+k}\) and the class marking technique.

Consider first formulas of the form (1). As in Lemma 12, the non-trivial case is \(\delta(x,y) = (x \neq y)\). Here, the different cases for \(\gamma(x)\) are more involved than those of (2) since there are more possibilities for the order constraints between \(x\) and \(y\). However, the reader should convince herself that the overall proof idea is the same as in Lemma 12.

For formulas as in Lemma 13, the only difference is that the \(\epsilon(x,y)\) subformulas are of one of the kinds \(x = y \pm j\) or \(x < y \pm j\), \(0 \leq j \leq k\). Once again, the overall proof idea remains the same. For example, if \(\delta(x,y) = (x \neq y)\) we use the 2 distinguished classes of \(\text{Lst}_{\beta}\) and \(\text{Lst}_{\beta}\) for \(\epsilon(x,y) = (x+j < y)\), and the predicate \(S_{+j}\) for \(\epsilon(x,y) = (x+j = y)\).

The proof of Theorem 20 implies that \(FO^2(\preceq,\prec,+\omega)\) is included in \(\text{E}MSO^2(\preceq,+1,\oplus 1)\), and since we provide a reduction of \(FO^2(\preceq,\prec,+\omega)\) to data automata. Recall that the logic \(\text{E}MSO^2(\preceq,+1,\oplus 1)\) is the extension of \(FO^2(\preceq,\prec,+1)\) by monadic second-order existential quantification and the class successor, and that this logic is equivalent to data automata (Prop. 14).

8.2 Infinite words

Another extension of interest, which might be useful e.g. for the verification of temporal properties, is the case of data \(\omega\)-words. A **data \(\omega\)-word** is simply an infinite sequence over \(\Sigma \times D\). In this section we show the following result.

**Theorem 21** Satisfiability of \(FO^2(\preceq,\prec,+1)\) formulas over data \(\omega\)-words is decidable.

The proof is along very similar lines as that of Theorem 3. We adapt data automata to infinite words, and we construct from an \(FO^2(\preceq,\prec,+1)\) formula a data \(\omega\)-automaton that recognizes the same language. We show that the string projection of the language defined by such an automaton is recognized by an extension of multicontext automata called \(B\ddot{u}chi\ bag\ machine\) (see below). Emptiness of this model is decidable by a reduction to emptiness of multicontext automata on finite words.

Data \(\omega\)-automata can be defined in analogy to data automata. We only mention the differences here. A **data \(\omega\)-automaton** \(D = (A,B_f,B_i)\) consists of (1) a base automaton \(A\) which is a \(B\ddot{u}chi\) letter-to-letter transducer with output over some alphabet \(\Gamma\), (2) a finitary class automaton \(B_f\) which is a finite word automaton over \(\Gamma\) and (3) an infinitary class automaton \(B_i\), which is a \(B\ddot{u}chi\) automaton over \(\Gamma\). A data \(\omega\)-word \(w\) is accepted if the base automaton has an accepting run over the string projection of \(w\) with output \(b_1b_2\cdots\) such that for every finite class \(i_1 < \cdots < i_k\),
The case when each class (using the predicate $16$ is
—The case as in Lemma 12 and each formula of the form
Proof. The proof follows the lines of the proof of Proposition 4: We first transform the formula
into Scott normal form and then transform each formula of the form $\forall x \forall y \xi$ into a data $\omega$-automaton
as in Lemma 12 and each formula of the form $\forall x \exists y \xi$ into a data $\omega$-automaton as in Lemma 13. The
Scott normalization step being identical, we will only explain the modifications needed in Lemmas
12 and 13. The basic difference when considering data $\omega$-words arises in subcases involving the
order relation between $x$ and $y$, with $x, y$ in different classes as the infiniteness of the word induces
more cases than in the finitary case. All other cases are treated similarly in the finitary and
infinitary case.
First, let $\psi$ be a formula as in Lemma 12:
\[
\forall x \forall y \left( (\alpha(x) \land \beta(y) \land \delta(x, y)) \rightarrow \gamma(x, y) \right).
\]
Recall that $\alpha$ and $\beta$ are types, $\delta$ is either $x \sim y$ or $x \neq y$, and $\gamma(x, y)$ is a disjunction of atomic
and negated atomic formulas that use only the order predicates $<$ and $+1$. The case when $\delta(x, y)$
is $x \sim y$ is solved like in the finitary case, using the predicate $S_{+1}$ which marks all positions $x$ such
that the successor position has the same data value. The only difference is that we now deal with
$\omega$-words. By Proposition 22 this test can be done by a data $\omega$-automaton. Using the predicate
$S_{+1}$ the formula $\psi$ amounts to a regular condition on each (finite or infinite) class, which can be
checked by suitable $B_f$ and $B_i$.
Thus, we assume now that $\delta(x, y)$ is $x \neq y$. We distinguish the same cases as in the proof of
Lemma 12.
—The case $\gamma(x, y) = false$ is completely analogous to the finitary case.
—Let $\gamma(x, y)$ be $x < y$. Here we distinguish two cases: (a) either there are only finitely many
$\alpha$-positions, and this case is completely analogous to the finitary case. Or, (b) the $\omega$-data word
contains infinitely many $\alpha$-positions. In the latter case, if $\text{Fst}_\beta(w)$ is defined, then all $\alpha$-positions
after $\text{Fst}_\beta(w)$ must be in the same class $c$ as $\text{Fst}_\beta(w)$. Moreover, there can be no $\beta$ outside $c$
and all $\alpha$ outside $c$ must be before $\text{Fst}_\beta$.
For (b) the base automaton guesses whether $\text{Fst}_\beta(w)$ is defined and marks its class, if this is
the case. It also checks that the marked class contains all (infinitely many) $\alpha$ after $\text{Fst}_\beta(w)$,
together with the remaining regular conditions above. The case $x \leq y + 1$ is handled similarly.
—For the cases where $\gamma(x, y)$ is $x = y + 1$, $x \neq y = 1$, or $x = y + 1 \lor y = x + 1$ we argue exactly
the same as in Lemma 12.
It remains to consider formulas $\psi$ as in Lemma 13:
\[
\forall x \exists y \left( \alpha(x) \rightarrow (\beta(y) \land \delta(x, y) \land \epsilon(x, y)) \right)
\]
The case when $\delta(x, y)$ is $x \sim y$ is treated as in Lemma 13, by checking a regular property on each
class (using the predicate $S_{+1}$ if needed). Therefore we consider only the case when $\delta(x, y)$
is $x \neq y$ (implying $x \neq y$):
—The case $\epsilon(x, y)$ is $x + 1 = y$ or $x = y + 1$ is solved as in Lemma 13: using $S_{+1}$, it is the base
automaton can check $\psi$.
Consider now the case where Proposition 24 finite words is equivalent to multicounter automata. If machine every position of the input word. Because the acceptance condition of the base automaton, using the class marking technique. Case (a) is handled as in the finitary case. For (b), \( A \) marks the class \( c \) with infinitely many \( \beta \) and checks that the last \( \alpha \) in \( c \) is at least two positions before the last \( \beta \) outside \( c \). For (c), there is nothing to do beyond checking that the guess was correct.

Consider now the case where \( \epsilon(x, y) \) is \( y + 1 < x \). If there is no occurrence of \( \beta \) in the data \( \omega \)-word \( w \), then \( \psi \) holds on \( w \) iff there is also no occurrence of \( \alpha \). If there is at least one occurrence of \( \beta \) (\( \text{Fst}_{\beta}(w) \) is defined) then we consider two cases. If \( \text{Fst}_{\beta}(w) \) is not defined then \( \psi \) holds on \( w \) iff all \( \alpha \) are in a different class than \( \text{Fst}_{\beta}(w) \) and there is no \( \alpha \) before \( \text{Fst}_{\beta}(w) + 2 \). If \( \text{Fst}_{\beta}(w) \) is defined then for each occurrence of \( \alpha \) to the right of \( \text{Fst}_{\beta}(w) + 2 \), either \( \text{Fst}_{\beta}(w) \) or \( \text{Fst}_{\beta}(w) \) is an appropriate value for \( y \) in \( \psi \). Hence \( \psi \) holds on \( w \) in this case iff there is no \( \alpha \) before \( \text{Fst}_{\beta}(w) + 2 \) and all \( \alpha \) between \( \text{Fst}_{\beta}(w) + 2 \) and \( \text{Fst}_{\beta}(w) + 2 \) are in a different class than \( \text{Fst}_{\beta}(w) \).

All these properties are easily testable by a data \( \omega \)-automaton by guessing the appropriate case and marking the classes of \( \text{Fst}_{\beta}(w) \) and \( \text{Fst}_{\beta}(w) \) as in the finitary case.

A B"uchi bag machine is defined as follows. It is a finite automaton with a finite number of bags. Each bag contains (finitely many) tokens, taken from an infinite set. The automaton reads (one-way) \( \omega \)-words without data values. A transition reads the current letter and, depending on the current state, performs a bag operation and changes the state, going to the right. Bag operations are of the following types:

- new(i): create a new token and place it in bag \( i \).
- move(i, j): move some token from bag \( i \) to bag \( j \).

In the move operation above, the token in bag \( i \) is chosen nondeterministically. In particular, transitions of the bag machine do not refer explicitly to token identities. For the acceptance condition, a set of accepting bags is distinguished. A run is accepting if each token created during a run is moved into an accepting bag infinitely often.

Before proceeding, we would like to sketch the analogy between B"uchi bag machines and multicounter automata. Each counter of a multicounter automaton represents a bag. An increment of a counter can be simulated by creating a new token in the corresponding bag. A decrement is simulated by moving a token from the corresponding bag to a (special) sink bag. We could also define bag machines on finite words; in the analogue a run is accepting if all tokens are in the accepting bags at the end of the run. It is fairly easy to see that this version of bag automata for finite words is equivalent to multicounter automata.

**Proposition 24** From each data \( \omega \)-automaton \( D \) a B"uchi bag machine recognizing the string projection of the language recognized by \( D \) can be computed.

**Proof.**

We simulate a data automaton \( D = (A, B_f, B_i) \) over data \( \omega \)-words with an effectively obtained B"uchi bag machine \( C \). The simulating machine \( C \) runs over string projections, and uses tokens to simulate data values. Let \( S \) be the set of states of the base automaton and \( Q \) be the set of states of the class automata (we assume that \( B_f, B_i \) have disjoint sets of states). The states of the bag machine \( C \) are the states \( S \) of the base automaton and \( C \) has a bag for each \( q \in Q \cup S \) plus an extra one, which is called looping bag. As in the proof of Proposition 5, the idea is to guess the output of the base automaton on-the-fly, while simulating the runs of the class automaton. The accepting bags are the looping bag, plus bags corresponding to accepting states of \( A \) and \( B_i \).

The transitions of \( C \) mimic the transitions of the base automaton \( A \), guessing its output for every position of the input word. Because the acceptance condition of \( C \) is defined by a set of
Fact 25 (Dickson’s lemma [Dickson 1913])

by the data automaton

content of the looping bag moves one token from the looping bag back into it.

the class automata creates or moves exactly one token among the

an output symbol and moves the token contained in the

into an accepting bag.

from the looping bag back into it. This operation ensures that these tokens can go infinitely

and refreshed infinitely often: in every transition, the machine non-deterministically moves a token

from the looping bag back into it. This operation ensures that these tokens can go infinitely often

into an accepting bag.

To sum up, a transition of \( C \) can be decomposed into three parts: one corresponding to \( A \) guesses

an output symbol and moves the token contained in the \( S \)-bags; one corresponding to the runs of the class automata creates or moves exactly one token among the \( Q \)-bags; and one refreshing the

content of the looping bag moves one token from the looping bag back into it.

From an accepting run of the Büchi bag machine one can reconstruct a data \( \omega \)-word accepted

by the data automaton \( D \) by looking at the evolution of tokens in bags from \( Q \) along the run.

□

For the decidability proof for Büchi bag machines we use the following well-known result:

Fact 25 (Dickson’s lemma [Dickson 1913]) For every infinite sequence of vectors \( (x_n)_{n \in \mathbb{N}} \subseteq \mathbb{N}^k \) there exists an infinite subsequence \( x_{i_1} \leq x_{i_2} \leq \cdots \), where \( \leq \) is the component-wise ordering.

Proposition 26 Emptiness is decidable for Büchi bag machines.

Proof. Fix a Büchi bag machine \( C \). We begin by showing that nonemptiness of \( C \) is equivalent
to a property \((*)\) holding for some finite words \( u, v \), with \( v \) non-empty. Then, we will show that

the latter can be reduced to emptiness of a multicounter automaton, and is therefore decidable.

Property \((*)\) of words \( u, v \) is defined as follows. There is a run \( \rho \) over \( uv \), with \( i \) being the position at the end of \( u \) and \( j \) being the position at the end of \( uv \), such that

(1) The states of the automaton as well as the sets of empty bags, are the same in positions \( i \) and

\( j \).

(2) For each non-empty bag in position \( i \) there is some token which passes through an accepting

bag between positions \( i \) and \( j \).

(3) Each non-empty bag at position \( i \) contains at least the same number of tokens at \( j \) as at \( i \).

We first show that property \((*)\) is necessary for nonemptiness. Consider an infinite word \( w \)
accepted by \( C \) and let \( \rho \) be the corresponding run. Since there is a finite number of bags and
states, we can extract an infinite sequence of positions where the states and the sets of empty bags
are the same. By Dickson’s Lemma this sequence has an infinite subsequence \( S \) in which, for each
bag, the number of tokens is non-decreasing. Let \( i \) be the first position in \( S \). Since the run is
accepting, each token that exists in position \( i \) eventually passes through an accepting state. Since
\( S \) is infinite, we can easily find an appropriate position \( j \in S \) fulfilling (1)-(3).

We now show that property \((*)\) is sufficient for nonemptiness of \( B \). To this end, let \( u, v \) be words
that satisfy property \((*)\). We claim that \( uv\omega \) is accepted by \( C \). The idea is to use a policy where
the move operation between bags is applied to the token in the bag that has not seen an accepting
bag for the longest time. Formally, we start with the run \( \rho_1 \) of \( C \) on \( uv \). Assume now that we
already defined, for \( i \in \mathbb{N} \), a run \( \rho_i \) of \( C \) on \( uv^i \), and we want to extend it to a run \( \rho_{i+1} = \rho_i \rho' \)

ACM Transactions on Computational Logic, Vol. V, No. N, Month 20YY.
on \(uv^{i+1}\). The subrun \(\rho'\) is obtained from the subrun \(\rho\) on \(v\) as follows. For each non-empty bag \(k\) at the end of \(\rho_i\), let \(t_k\) be a token for which the number of steps without being in an accepting bag is maximal within the tokens of \(k\). The subrun \(\rho'\) is obtained from \(\rho\) such that token \(t_k\) goes through an accepting bag.

It is not hard to see that in the resulting run on \(uv^\omega\) each token passes through an accepting bag infinitely often. Assume otherwise that some token \(t\) passes only finitely often through an accepting bag. We can choose \(t\) such that the last step \(i\) in which \(t\) passes through an accepting bag is minimal (if \(t\) never does so let \(i\) be the step before \(t\) is created). Obviously, \(t\) will be the “minimal token” in its bag after a finite number of steps and thus will pass through an accepting bag, the desired contradiction.

Note that we have also shown here that every nonempty Büchi bag machine accepts an ultimately periodic word, if any.

It remains to show how it can be decided whether there exist finite words \(u, v\) with property (*). We reduce this problem to the emptiness of a multicounter automaton \(M\) over finite words. For every pair of bags \(k, l\) in the automaton \(C\), the automaton \(M\) will have counters \(b_{k,l}, c_{k,l}\) and \(d_l\). At the beginning, \(M\) reads its input—corresponding to the word \(u\)—and simulates the run of \(C\), so that for every bag \(k\) of \(C\), the value of counter \(c_{k,k}\) contains the size of bag \(k\). (The other counters have value zero.) At some point, \(M\) nondeterministically guesses that it finished reading \(u\). Let \(i\) refer to this position. It then reads the rest of its input, which corresponds to the word \(v\). Between positions \(i\) and \(j\) (the end of the input \(uv\)), the counter values are interpreted as follows:

- \(b_{k,l}\): The number of tokens currently in bag \(l\) that were in bag \(k\) at position \(i\) and have passed through an accepting bag since position \(i\).
- \(c_{k,l}\): The number of tokens currently in bag \(l\) that were in bag \(k\) at position \(i\) and have not passed through an accepting bag since position \(i\).
- \(d_l\): The number of tokens currently in bag \(l\) that were created after position \(i\).

Here and in the following, we do not distinguish notationally the value of a counter from the counter itself. Note that at any point between positions \(i\) and \(j\) we can recover the number \(a_k\) of tokens that were in bag \(k\) at position \(i\), this number is

\[
a_k = \sum_l (b_{k,l} + c_{k,l}) .
\]

We can also know the number of tokens currently in bag \(l\), which is

\[
d_l + \sum_k (b_{k,l} + c_{k,l}) .
\]

It is not difficult to define the transitions of \(M\) so that the intended properties of the counters are satisfied. For example, the transition of \(M\) that decrements \(b_{k,l}\) and increments \(c_{k,l}\) simulates the move from the bag \(l\) to a bag \(l'\) of a token created before position \(i\), which has passed through an accepting bag since position \(i\) and which was in bag \(k\) at position \(i\). In order to capture property (*), the automaton should accept if: the states of \(C\) were the same in positions \(i\) and \(j\), which is easy for the automaton to check; and for each bag \(k\), both properties (3) and (4) below are satisfied:

\[
a_k \leq d_k + \sum_l (b_{l,k} + c_{l,k}) \tag{3}
\]

\[
a_k = d_k = 0 \quad \text{or} \quad \sum_l b_{k,l} > 0 \tag{4}
\]

We have produced a multicounter automaton where the acceptance condition is a boolean combination of linear inequalities on its counters. As we will explain next, emptiness for this extended model of multicounter automata can be reduced to emptiness for the usual model (introduced above) where the acceptance condition requires all counters to have value zero at the end of the run.
First, we can convert the boolean combination to DNF, so that we may assume that the property to check at the end of the run is a conjunction of linear inequalities. By using copies of counters we may assume that each counter occurring in the acceptance condition appears in a unique inequality. The last step is to simulate each inequality by zero tests. Each inequality \( \sum_{c \in C} c \leq \sum_{d \in D} d \) can be checked by decrementing in parallel (and non-deterministically) one counter from \( C \) and one from \( D \). Then we stop decrementing \( C \) and continue with \( D \) only, until all counters are zero. \( \square \)

9. UNDECIDABLE EXTENSIONS

In this section we show that many immediate extensions of the logic lead to undecidability. We first consider the case of several equivalence relations. In XML, document nodes may have several different attributes, which are accessed via the query languages. Equality tests between node attributes could be simulated using several equivalence relations. For instance checking that the nodes \( x \) and \( y \) agree on attribute \( a \) could be written as \( x \sim_a y \). However, in [Kieroński and Otto 2005] it is shown that two-variable logic is undecidable with three equivalence relations and some unary relations. In the presence of the successor and the linear order, two equivalence relations already yield undecidability:

**Proposition 27** Satisfiability of FO\(^2\)(\(\sim_1, \sim_2, <, +1\)) and of FO\(^2\)(\(\sim_1, \sim_2, +1, +2, +3\)) formulas over data words is undecidable.

**Proof.** In the following, 2-data-words are finite sequences over \( \Sigma \times D \times D \), i.e., each position carries two data values. Below, we write \( i\)-class when talking about the equivalence class of the relation \( \sim_i \), for \( i = 1, 2 \).

The proof is by a reduction from Post’s Correspondence Problem (PCP). An instance of PCP consists of \( k \) pairs \((u_i, v_i)\) of words from \( \Sigma^* \) and the question is whether there exists a non-empty, finite sequence of indices \( i_0, \ldots, i_n \) such that \( u_{i_0}u_{i_1} \cdots u_{i_n} = v_{i_0}v_{i_1} \cdots v_{i_n} \).

Let \( \Sigma' = \Sigma \cup \Sigma' \) be the alphabet consisting of two disjoint copies of \( \Sigma \). If \( w \) is a word in \( \Sigma^* \), then \( \overline{w} \in \Sigma^* \) is obtained from \( w \) by replacing each letter with the corresponding one in \( \Sigma \). Consider a solution \( i_0, \ldots, i_n \) for the given PCP instance. Let \( w \) be the word \( u_{i_0}u_{i_1} \cdots u_{i_n} \), or equivalently the word \( v_{i_0}v_{i_1} \cdots v_{i_n} \). Without loss of generality we assume that if there is a solution, then there is one where \( w \) is of odd length. To this end, for each pair \((u_i, v_i)\) an additional pair \((\$u_i, \$v_i)\) can be added, where \$ is a new symbol. Thus, for each solution \( w \) without \$, the word \$w is a solution as well, and if the original system had no solutions, the new system will not have any solution either.

We encode this solution by a data word \( \hat{w} \) satisfying the following:

— The string projection \( \text{str}(\hat{w}) \) is \( u_0\overline{v_m} \cdots u_n\overline{v_m} \). In particular, the sequence of letters from \( \Sigma \) is the same as the sequence of letters from \( \overline{\Sigma} \).

— The subsequence of pairs of values in \( w \) is the same as the one in \( \overline{w} \), and it is of the form \((\alpha_1, \beta_1)(\alpha_2, \beta_2)(\alpha_3, \beta_3) \ldots (\alpha_{m-1}, \beta_{m-1})(\alpha_m, \beta_m)\) where all \( \alpha_i \) (\( \beta_i \), respectively) are different.

We describe first a formula of FO\(^2\)(\(\sim_1, \sim_2, <, +1\)) such that \( w \) is a solution of PCP iff \( \hat{w} \) is a model of the formula. The formula is the conjunction of the following properties:

1. The string projection belongs to \( \{u_i\overline{v_i} \mid 1 \leq i \leq k\}^+ \). This is easy to do in FO\(^2\)(+1).

2. The values in the \( \Sigma \)-subword are such that:
   a. Each 1-class has 2 elements with a label in \( \Sigma \), except for the last \( \Sigma \)-position, which has a 1-value that occurs only once.
   b. Each 2-class has 2 elements with a label in \( \Sigma \), except for the first \( \Sigma \)-position, which has a 2-value that occurs only once.
   c. For every \( \Sigma \)-position but the first and the last one: either there exist a \( \Sigma \)-position to its right (relative to \( < \)) in the same 1-class and a \( \Sigma \)-position to its left (relative to \( < \)) in the same 2-class, or the same with 1 and 2 interchanged.

3. The same properties as in (2) are required for the \( \overline{\Sigma} \)-subword.

ACM Transactions on Computational Logic, Vol. V, No. N, Month 20YY.
Finally, each pair of data values of the $\Sigma$-subword appears also in the $\overline{\Sigma}$-subword with the same letter, and conversely.

It is not hard to verify now that property (2) ensures that the sequence of pairs of data in the $\Sigma$-subword is of the form

$$(\alpha_1, \beta_1)(\alpha_1, \beta_2)(\alpha_2, \beta_2)(\alpha_2, \beta_3) \ldots (\alpha_{m-1}, \beta_m)(\alpha_m, \beta_m)$$

To see this, we can construct a directed graph where the vertices are the $\Sigma$-positions and there is an edge from $x$ to $y$ iff $x < y$ and they are in the same 1-class or 2-class. Because of formula (2), every node but the first and the last one has in-degree 1 and out-degree 1 (the first node has indegree 0 and outdegree 1, and the last one has indegree 1 and outdegree 0). Therefore, the graph must corresponds to the natural successor relation on the $\Sigma$-positions.

Since we have the same property in the $\Sigma$-subword, and together with formula (4), the sequence of data values and letters is the same in the $\Sigma$-subword and the $\overline{\Sigma}$-subword, hence we obtain a solution of PCP.

If the order relation $<$ is replaced by relations for the $+2$, $+3$ successors, the above undecidability proof can be easily adapted. To simplify matters we assume that the PCP instance consists of words of length at most 2. It is well-known that PCP is still undecidable in this case [Hopcroft and Ullman 1979]. We use the same encoding. The only difference is the way to ensure that the sequence of pairs of data in the $\Sigma$-subword (respectively $\overline{\Sigma}$-subword) is of the form

$$(\alpha_1, \beta_1)(\alpha_1, \beta_2)(\alpha_2, \beta_2)(\alpha_2, \beta_3) \ldots (\alpha_{m-1}, \beta_m)(\alpha_m, \beta_m)$$

We can now enforce directly that the sequence of 1-values in the $\Sigma$-subword is of the form $\alpha_1\alpha_1\alpha_2\alpha_2\ldots \alpha_m$ (and similarly for the 2-values), with distinct $\alpha_i$. For this, it suffices to replace the last requirement of property (2) by the following one: each 1-class with 2 elements is such that these positions are either adjacent, or separated by $\overline{\Sigma}$-letters only. Since at most 2 such letters can occur continguously, the claim follows.

With only one equivalence relation, three variables already yield undecidability, even without linear order.

**Proposition 28** Satisfiability of $\text{FO}^3(\sim, +1)$ formulas over data words is undecidable.

Note that this implies the undecidability of satisfiability for $\text{FO}^3(\sim, <)$, and of course of $\text{FO}^3(\sim, +1, <)$, since the relation $+1$ is definable from $<$ with three variables.

**Proof.** One way of proving the proposition would be by a reduction from the undecidable logic $\text{FO}^2(\sim_1, \sim_2, +1, +2, +3)$ (recall Proposition 27). To implement two data values, each position is split into two consecutive positions, with the second position having a special dummy label. Using three variables, we can then simulate any relation $+k$.

Below we present a more direct proof, which will also be referenced in Proposition 29.

We reduce PCP to satisfiability of $\text{FO}^4(\sim_1, +1)$. We slightly modify the coding of Proposition 27 to deal with the fact that each position of the word carries only one data value.

The idea is that each class will contain two positions, these will be used to match the appropriate positions in the words $\tilde{w}$ and $\overline{\pi}$. More formally, a solution will be encoded by a data word $\tilde{w}$ with labels from $\Sigma'$ satisfying the following:

---

The string projection of $\tilde{w}$ belongs to $\{u_i\overline{\pi} \mid 1 \leq i \leq k\}^+$. This can be easily expressed by a formula of $\text{FO}^4(+1)$.

---

The $\Sigma$-positions ($\overline{\Sigma}$-positions, respectively) carry different data values. Moreover, the sequence of data values in the $\Sigma$-subword is the same as the one in the $\overline{\Sigma}$-subword. The former can be expressed by using only two variables; it is the latter condition for which we need a third variable. We express that for every pair of data values in consecutive $\Sigma$-positions, their matching occurrences with labels in $\Sigma$ are also consecutive:

$$\forall x \forall y \text{ Succ}(y, x) \rightarrow (\exists z \ x \sim z \land (\exists x \text{ Succ}(x, z) \land x \sim y))$$

ACM Transactions on Computational Logic, Vol. V, No. N, Month 20YY.
Here, $\text{Succ}(y, x)$ $(\text{Succ}(y, x))$, respectively expresses $x, y$ are consecutive $\Sigma$-positions $(\Sigma$-positions, respectively). This can be done without the order or additional successor predicates, because the distance between $x$ and $y$ is bounded by the maximal length of a PCP word and because we can use three variables.

Another possible extension is to add a binary predicate to the signature which is interpreted as a linear order on the data values. However, it is not hard to see that this also yields undecidability, even for $\text{FO}^2$.

**Proposition 29**  
Satisfiability of $\text{FO}^2(\sim, \prec, +1, <)$ formulas over data words is undecidable.

**Proof.** We revisit the proof of Proposition 28. We use the same coding of PCP and recall that only the last formula, which checks that the two sequences of data values (the one for symbols in $\Sigma$ and the one for symbols in $\overline{\Sigma}$) are the same, uses three variables. With the help of $<$ this can be replaced by a formula which checks that, for both sequences, the data values are in increasing order: $\forall x, y \ \Sigma(x) \land \Sigma(y) \land x < y \rightarrow x < y$ (and similarly for $\overline{\Sigma}$). □

10. DISCUSSION

We have shown that satisfiability of $\text{FO}^2(\sim, \prec, +1)$ over data words is decidable. It follows immediately that also $\text{EMSO}^2(\sim, \prec, +1)$ is decidable over such models.

In the absence of data values, $\text{FO}^2(+1, <)$ has several equivalent characterizations, for instance it corresponds to the fragment of LTL that uses only unary temporal predicates [Etessami et al. 2002]. Still in the absence of data values, $\text{EMSO}^2(+1, <)$ has the same expressive power as MSO.

In a sense the decidability of $\text{EMSO}^2(\sim, <, +1)$ can be seen as an extension of classical decidability result of MSO over strings.

An interesting side result is the connection between $\text{FO}^2(\sim, <, +1)$ and multicontext automata (and therefore Petri nets). Indeed, string projections of the languages defined by $\text{FO}^2(\sim, <, +1)$ formulas are recognized by multicontext automata. The converse is true when the logic is extended to $\text{EMSO}^2(\sim, <, +1, \oplus 1)$, which has the same expressive power as $\text{EMSO}^2(\sim, <, +1)$. It would be interesting to understand the connection between the two formalisms, because of the connection with Petri nets pinpointing the complexity of satisfiability is likely to be difficult.

Our reduction from the decidability of $\text{FO}^2(\sim, <, +1)$ to emptiness of multicontext automata is in $2\text{EXPTime}$. We do not know whether this is optimal or not.

If only one of the two predicates $+1$ and $<$ is used, the decision problem is elementary. As shown in this paper, satisfiability is $\text{NEXPTime}$-complete for $\text{FO}^2(\sim, <)$. In [Bojańczyk et al. 2006] we studied the logic $\text{FO}^2(\sim, +1)$, and gave a $3\text{NEXPTime}$ algorithm for satisfiability over unranked ordered trees. This immediately gives a $3\text{NEXPTime}$ upper bound for satisfiability of $\text{FO}^2(\sim, +1)$ over words, although we conjecture that the algorithm can be improved to $2\text{NEXPTime}$, or even further, if only words are considered. The logic $\text{FO}^2(\sim, +1)$ was also considered in [Björklund and Bojańczyk 2007b], which considered words with several data values. It turns out that if the data values are such that the appropriate equivalence relations are successive refinements, then satisfiability is decidable as for $\text{FO}^2(\sim, +1)$.

Whether $\text{FO}^2(\sim, <, +1)$ is decidable over trees is still an open question which was shown in [Bojańczyk et al. 2006] to be at least as hard as checking emptiness of multicontext automata over trees (stated as an open question in [Groote et al. 2004]). One decidable variant of satisfiability for $\text{FO}^2(\sim, <, +1)$ for trees is the bounded depth case, considered in [Björklund and Bojańczyk 2007a]: if only trees of fixed depth $k$ are considered, then satisfiability is decidable, regardless of the choice of $k$.
