Abstract

We propose a game-theoretic dynamics of a population of replicating individuals. It consists of two parts: the standard replicator one and a migration between two different habitats. We consider symmetric two-player games with two evolutionarily stable strategies: the efficient one in which the population is in a state with a maximal payoff and the risk-dominant one where players are averse to risk. We show that for a large range of parameters of our dynamics, even if the initial conditions in both habitats are in the basin of attraction of the risk-dominant equilibrium (with respect to the standard replication dynamics without migration), in the long run most individuals play the efficient strategy.

1. Introduction

The long-run behavior of interacting individuals can often be described within game-theoretic models. Players with different behaviors (strategies) receive payoffs interpreted as the number of their offspring. Maynard Smith and Price (1973) (see also Maynard Smith, 1982) introduced the fundamental notion of evolutionarily stable strategy. If everybody plays such a strategy, then a small number of mutants playing a different one is eliminated from the population. The dynamical interpretation of an evolutionarily stable strategy was later provided by several authors (Taylor and Jonker, 1978; Hofbauer et al., 1979; Zeeman, 1981). They proposed a system of differential equations, the so-called replicator equations, which describe time-evolution of frequencies of strategies. It is known that any evolutionarily stable strategy is an asymptotically stable stationary point of such dynamics (Weibull, 1995; Hofbauer and Sigmund, 1998, 2003).

We analyse symmetric two-player games with two evolutionarily stable pure strategies and a unique unstable mixed Nash equilibrium. The efficient strategy (called also payoff dominant), when played by the whole population, results in the highest possible payoff (fitness). The risk-dominant one is played by individuals averse to risk. The strategy is risk dominant if it has a higher expected payoff against a player playing both strategies with equal probabilities than the other one (the notion of the risk dominance was introduced and thoroughly studied by Harsányi and Selten (1988)).

Typical example is that of a modified stag-hunt game, where two players choose simultaneously one of two actions: either to join the stag hunt (strategy S) or to go after a hare (strategy H). The strategy S gives the highest possible payoff provided both players join the stag hunt and split the reward. However, when the other player is not loyal and switches to H , then the one playing S receives nothing. The strategy H yields lower but less risky payoffs with a higher payoff when the other player also chooses H . Such a coordination game has two pure Nash equilibria: the efficient one, where all players choose S , and the one in which players are

averse to risk, and play *H*. Both strategies are evolutionarily stable and therefore we are faced with the problem of equilibrium selection—which strategy will be played in the long run?

In the replicator dynamics, both strategies are locally asymptotically stable, with the risk-dominant one having a bigger basin of attraction. Here, we propose a dynamical model for which the efficient strategy has a much larger basin of attraction than the risk-dominant one.

We consider a large population of identical individuals who at each time step can belong to one of two different non-overlapping subpopulations or habitats which differ only by their replication rates. In both habitats they play the same two-player symmetric game. Our population dynamics consists of two parts: the standard replicator one and a migration between subpopulations. Individuals are allowed to change their habitats. They move to a habitat in which the average payoff of their strategy is higher; they do not change their strategies.

Migration can help the population to evolve towards an efficient equilibrium. Below we briefly describe the possible mechanism responsible for it. If in a subpopulation, the fraction of individuals playing the efficient strategy *A* is above its unique mixed Nash equilibrium fraction, then the expected payoff of *A* is bigger than that of *B* in this subpopulation, and therefore the subpopulation evolves to the efficient equilibrium by the replicator dynamics without any migration. Let us assume therefore that such fraction is below the Nash equilibrium in both subpopulations. Without loss of generality we assume that initial conditions are such that the fraction of individuals playing *A* is bigger in the first subpopulation than in the second one. Hence the expected payoff of *A* is bigger in the first subpopulation than in the second one, and the expected payoff of *B* is bigger in the second subpopulation than in the first one. This implies that a fraction of *A*-players in the second population will switch to the first one and at the same time a fraction of *B*-players from the first population will switch to the second one—migration causes the increase of the fraction of individual of the first population playing *A*. However, any *B*-player will have more offspring than any *A*-player (we are below a mixed Nash equilibrium) and this has the opposite effect on relative number of *A*-players in the first population than the migration. The asymptotic composition of the whole population depends on the competition between these two processes.

In this note, we derive sufficient conditions for migration and replication rates such that the whole population will be in the long run in a state in which most individuals occupy only one habitat (the first one for the above described initial conditions) and play the efficient strategy.

In Section 2, we introduce the notation and present the class of games we consider. In Section 3, we propose a discrete-time model, obtain its continuous counterpart and prove our results. Section 4 contains a short discussion.

2. Replicator dynamics

We consider two-player symmetric games with two pure strategies and two symmetric Nash equilibria. A payoff matrix is given by

$$U = \begin{matrix} & \begin{matrix} A & B \end{matrix} \\ \begin{matrix} A \\ B \end{matrix} & \begin{matrix} a & b \\ c & d \end{matrix} \end{matrix},$$

where the *ij* entry, *i, j = A, B*, is the payoff of the first (row) player when he plays the strategy *i* and the second (column) player plays the strategy *j*; payoffs of the column player are given by the matrix transposed to *U*.

An assignment of strategies to both players is a Nash equilibrium, if for each player, for a fixed strategy of his opponent, changing the current strategy cannot increase his payoff.

In order to use our payoff matrix in the dynamics of reproducing species, we assume that all payoffs are nonnegative. We also assume that $a > d > c$, $d > b$, and $a + b < c + d$ which implies in particular that (A, A) and (B, B) are two strict Nash equilibria hence both *A* and *B* are evolutionarily stable. The last inequality means that an expected payoff of *B* against a player playing both strategies with equal probabilities is higher than that of *A*. We address the problem of equilibrium selection between the payoff-dominant (efficient) equilibrium (A, A) and the risk dominant (B, B) . Our assumptions imply also that a *B*-player receives a maximal payoff when he plays against another *B*-player.

As an example, consider the following payoffs: $a = 4$, $b = 0$, $c = 2$, $d = 3$. The strategy profile (A, A) is more risky than (B, B) since from the point of view of the row player, a deviation by the column player in (A, A) results in a payoff loss of 4 units versus a loss of 1 in (B, B) .

In the replicator dynamics, individuals of a large population are matched many times to play the above described stage game. Let *x* be the fraction of the population playing *A*. The expected payoff of *A* is given by $f_A = ax + b(1 - x)$ and that of *B* by $f_B = cx + d(1 - x)$. A mixed Nash equilibrium strategy is such x^* that the above two expected values are equal, hence $x^* = (d - b)/(d - b + a - c)$. In the standard replicator dynamics, the rate of change of *x* is proportional to the expected payoff of *A*. The corresponding differential equation reads (Weibull, 1995;

Hofbauer and Sigmund, 1998)

$$\frac{dx}{dt} = x(f_A - f_B) = x(1 - x)(x - x^*). \quad (1)$$

If the initial condition $x(0) < x^*$, then the population evolves in time to the state $x = 0$, i.e. in the long run almost all individuals will play B . If $x(0) > x^*$, then $x = 1$ is an attracting point of the dynamics. If B is risk dominant, then $x^* > \frac{1}{2}$, hence B has a bigger basin of attraction than A .

Below, we propose an evolutionary dynamics for which an efficient strategy has a much bigger basin of attraction than the risk-dominant one.

3. Mixed replicator dynamics with migration

We consider a large population of identical individuals who at each time step can belong to one of two different subpopulations or habitats. In both subpopulations they play the same two-player symmetric game. Our population dynamics consists of two parts: the standard replicator one which represents slow evolutionary changes and a migration between two habitats. Let δ be a time step. We allow two subpopulations to replicate with different speeds. We assume that during time-step δ , a fraction δ of the first subpopulation and a fraction $\kappa\delta$ of the second subpopulation plays the game and receives payoffs which are interpreted as the number of their offspring. Moreover, we allow a fraction of individuals to migrate to a habitat in which their strategies have a higher expected payoff.

Let r_s^i denote the number of individuals which use the strategy $s \in \{A, B\}$ in the subpopulation $i \in \{1, 2\}$. By f_s^i we denote the expected payoff of the strategy s in the subpopulation i :

$$f_A^1 = ax + b(1 - x), \quad f_B^1 = cx + d(1 - x),$$

$$f_A^2 = ay + b(1 - y), \quad f_B^2 = cy + d(1 - y),$$

where

$$x = \frac{r_A^1}{r_1}, \quad y = \frac{r_A^2}{r_2}, \quad r_1 = r_A^1 + r_B^1, \quad r_2 = r_A^2 + r_B^2,$$

x and y denote fractions of A -players in the first and second population, respectively. We denote by $\alpha = r_1/r$ the fraction of the whole population in the first subpopulation, where $r = r_1 + r_2$ is the total number of individuals.

The evolution of the number of individuals in each subpopulation is assumed to be a result of the replication and the migration flow. In our model, the direction and intensity of migration of individuals with a given strategy will be determined by the difference of the expected payoffs of that strategy in both habitats. Individuals will migrate to a habitat with a higher

payoff. The evolution equations for the number of individuals playing strategy s , $s \in \{A, B\}$, in habitat i , $i \in \{1, 2\}$, have the following form:

$$r_A^1(t + \delta) = R_A^1 + \Phi_A, \quad (2)$$

$$r_B^1(t + \delta) = R_B^1 + \Phi_B, \quad (3)$$

$$r_A^2(t + \delta) = R_A^2 - \Phi_A, \quad (4)$$

$$r_B^2(t + \delta) = R_B^2 - \Phi_B, \quad (5)$$

where all functions on the right-hand sides are calculated at time t .

Functions R_s^i describe an increase of the number of the individuals playing strategy s in the subpopulation i due to replication (cf. Weibull, 1995):

$$R_s^1 = (1 - \delta)r_s^1 + \delta f_s^1 r_s^1, \quad s \in \{A, B\}, \quad (6)$$

$$R_s^2 = (1 - \kappa\delta)r_s^2 + \kappa\delta f_s^2 r_s^2, \quad s \in \{A, B\}. \quad (7)$$

The rate of replication of the individuals playing strategy s in the first subpopulation is given by δf_s^1 , and in the second subpopulation by $\kappa\delta f_s^2$. The parameter κ measures the difference of reproduction speeds in both habitats.

Functions Φ_s , $s \in \{A, B\}$, are defined by

$$\Phi_s = \delta\gamma(f_s^1 - f_s^2)[r_s^2\Theta(f_s^1 - f_s^2) + r_s^1\Theta(f_s^2 - f_s^1)], \quad (8)$$

where Θ is the Heaviside's function,

$$\Theta(x) = \begin{cases} 1, & x \geq 0, \\ 0, & x < 0. \end{cases} \quad (9)$$

Functions Φ_s describe changes of the numbers of the individuals playing strategy s in the relevant habitat due to migration. Φ_s will be referred to as the migration of individuals (who play strategy s) between the habitats.

Thus, if for example $f_A^1 > f_A^2$, then there is a migration of individuals with strategy A from the second habitat to the first one:

$$\Phi_A = \delta\gamma r_A^2(f_A^1 - f_A^2) \quad (10)$$

and since then necessarily $f_B^1 < f_B^2$ [note that $f_A^1 - f_A^2 = (a - b)(x - y)$ and $f_B^1 - f_B^2 = (c - d)(x - y)$], there is a migration flow of individuals with strategy B from the first habitat to the second one:

$$\Phi_B = \delta\gamma r_B^1(t)(f_B^1 - f_B^2). \quad (11)$$

In this case, the migration flow Φ_A describes the increase of the number of individuals which play strategy A in the first subpopulation due to migration of the individuals playing strategy A in the second subpopulation. This increase is assumed to be proportional to the number of individuals playing strategy A in the second subpopulation and the difference of payoffs of this strategy in both subpopulations. The constant of proportionality is δ times the rate of migration γ .

The case $\gamma = 0$ corresponds to two separate populations which do not communicate and evolve independently. Our model reduces then to the standard discrete-time replicator dynamics (Weibull, 1995). In this case, the total number of players who use a given strategy changes only due to the increase or decrease of the strategy fitness, as described by functions defined in Eqs. (6) and (7).

In the absence of replication, $\delta = 0$, there is a conservation of the number of individuals playing each strategy in the whole population. This corresponds to our model assumption that individuals cannot change their strategies but only habitats in which they live.

For $f_A^1 > f_A^2$ we obtain from Eqs. (2)–(5) equations for $r_i(t)$ and $r(t)$:

$$r_1(t + \delta) = (1 - \delta)r_1(t) + \delta r_1(t) \left[\frac{r_A^1 f_A^1 + r_B^1 f_B^1}{r_1} + \gamma \frac{r_A^2 (f_A^1 - f_A^2) + r_B^1 (f_B^1 - f_B^2)}{r_1} \right], \tag{12}$$

$$r_2(t + \delta) = (1 - \kappa\delta)r_2(t) + \delta r_2(t) \left[\kappa \frac{r_A^2 f_A^2 + r_B^2 f_B^2}{r_2} + \gamma \frac{r_A^2 (f_A^2 - f_A^1) + r_B^1 (f_B^2 - f_B^1)}{r_2} \right], \tag{13}$$

$$r(t + \delta) = (1 - \delta)r_1(t) + (1 - \kappa\delta)r_2(t) + \delta r(t) \times \left[\alpha \left(\frac{r_A^1 f_A^1}{r_1} + \frac{r_B^1 f_B^1}{r_1} \right) + (1 - \alpha)\kappa \left(\frac{r_A^2 f_A^2}{r_2} + \frac{r_B^2 f_B^2}{r_2} \right) \right], \tag{14}$$

where all functions in square brackets depend on t .

Now, as in the derivation of standard replicator dynamics (cf. e.g. Weibull, 1995), we consider the frequencies of the individuals playing the relevant strategies in both habitats rather than their numbers. Thus, we focus on the temporal evolution of the frequencies, x and y , and the relative size of the first subpopulation, α . We divide Eq. (2) by Eq. (12), Eq. (4) by Eq. (13), and Eq. (12) by Eq. (14). Performing the limit $\delta \rightarrow 0$ we obtain the following differential equations:

$$\frac{dx}{dt} = x \left[(1 - x)(f_A^1 - f_B^1) + \gamma \left[\left(\frac{y(1 - \alpha)}{x\alpha} - \frac{y(1 - \alpha)}{\alpha} \right) \times (f_A^1 - f_A^2) - (1 - x)(f_B^1 - f_B^2) \right] \right], \tag{15}$$

$$\frac{dy}{dt} = y \left[\kappa(1 - y)(f_A^2 - f_B^2) + \gamma \left[(1 - y)(f_A^2 - f_A^1) - \frac{(1 - x)\alpha}{1 - \alpha} (f_B^2 - f_B^1) \right] \right], \tag{16}$$

$$\begin{aligned} \frac{d\alpha}{dt} = & \alpha(1 - \alpha)[xf_A^1 + (1 - x)f_B^1 - (yf_A^2 + (1 - y)f_B^2)] \\ & + \alpha\gamma \left[\frac{y(1 - \alpha)}{\alpha} (f_A^1 - f_A^2) + (1 - x)(f_B^1 - f_B^2) \right] \\ & + \alpha(1 - \alpha)(\kappa - 1)(1 - yf_A^2 - (1 - y)f_B^2). \end{aligned} \tag{17}$$

Similar equations are derived for the case $f_A^1 < f_A^2$ (since our model is symmetric with respect to the permutation of the subpopulations, it is enough to renumerate the relevant indices and redefine the parameter κ).

Assume first that $f_A^1(0) > f_A^2(0)$, which is equivalent to $x(0) > y(0)$. It follows from Eqs. (2)–(5) that a fraction of A -players from the subpopulation 2 will migrate to the subpopulation 1 and a fraction of B -players will migrate in the opposite direction. This will cause x to increase and y to decrease. However, if $x(0) < x^*$ and $y(0) < x^*$, then $f_A^1 < f_B^1$ and $f_A^2 < f_B^2$, therefore B -players will have more offspring than A -players. This has the opposite effect on the relative number of A -players in the first subpopulation than migration. If $x(0) < y(0)$, then migration takes place in the reverse directions.

The outcome of the competition between migration and replication depends, for a given payoff matrix, on the relation between $x(0) - y(0)$, γ and κ . We are interested in formulating sufficient conditions for the parameters of the model, for which most individuals of the whole population will play in the long run the efficient strategy A . We prove the following theorem.

Theorem. *If*

$$\gamma[x(0) - y(0)] > \max \left[\frac{d - b}{d - c}, \frac{\kappa(a - c)}{a - b} \right],$$

then $x(t) \rightarrow_{t \rightarrow \infty} 1$ and $y(t) \rightarrow_{t \rightarrow \infty} 0$. If $\kappa < (a - 1)/(d - 1)$, then $\alpha(t) \rightarrow_{t \rightarrow \infty} 1$.

If

$$\gamma[y(0) - x(0)] > \max \left[\frac{\kappa(d - b)}{d - c}, \frac{a - c}{a - b} \right],$$

then $x(t) \rightarrow_{t \rightarrow \infty} 0$ and $y(t) \rightarrow_{t \rightarrow \infty} 1$. If $\kappa > (d - 1)/(a - 1)$, then $\alpha(t) \rightarrow_{t \rightarrow \infty} 0$.

Proof. Assume first that $x(0) > y(0)$. From Eqs. (15) and (16) we get the following differential inequalities:

$$\frac{dx}{dt} > x(1 - x)[f_A^1 - f_B^1] + \gamma(f_B^2 - f_B^1), \tag{18}$$

$$\frac{dy}{dt} < y(1 - y)[\kappa(f_A^2 - f_B^2) + \gamma(f_A^2 - f_A^1)]. \tag{19}$$

Using explicit expressions for f_s^i we get

$$\begin{aligned} \frac{dx}{dt} > & x(1 - x)[(a - c + d - b)x + b - d \\ & + \gamma(d - c)(x - y)], \end{aligned} \tag{20}$$

$$\frac{dy}{dt} < y(1-y)[\kappa[(a-c+d-b)y + b-d] - \gamma(a-b)(x-y)]. \quad (21)$$

We note that if $\gamma(d-c)(x(0)-y(0)) > d-b$ then $\gamma(d-c)(x(0)-y(0)) + b-d + (a-c+d-b)x(0) > 0$, i.e. $dx/dt(0) > 0$.

Analogously, if $\gamma(a-b)(x(0)-y(0)) > \kappa(a-c)$, then $\gamma(a-b)(x(0)-y(0)) > \kappa[(a-c+d-b) + b-d] > \kappa[(a-c+d-b)y(0) + b-d]$, therefore $dy/dt(0) < 0$. Thus, combining both conditions we conclude that $x(t) - y(t)$ is an increasing function so $x(t) > y(t)$ for all $t \geq 0$, hence we may use Eqs. (15)–(17) all the time. We get that $x(t) \rightarrow_{t \rightarrow \infty} 1$ and $y(t) \rightarrow_{t \rightarrow \infty} 0$, and the first part of the thesis follows. Now from Eq. (17) it follows that if $a-d + (\kappa-1)(1-d) > 0$, i.e. $\kappa < (a-1)/(d-1)$, then $\alpha(t) \rightarrow_{t \rightarrow \infty} 1$.

The second part of our theorem, corresponding to initial conditions $y(0) > x(0)$, can be proved analogously, starting from Eqs. (2)–(5) written for the case $f_A^1(0) < f_A^2(0)$ and their continuous counterparts. We omit details. \square

The above conditions for κ mean that the population consisting of just *A*-players replicates faster [exponentially in $(a-1)t$] than the one consisting of just *B*-players [exponentially in $(d-1)\kappa t$]. The same results would follow if the coefficients of the payoff matrix of the game played in one habitat would differ from those in the second habitat by an additive constant.

We have shown that for γ and the difference of the initial conditions $x(0) - y(0)$ satisfying certain inequalities, the fraction of *A*-players in one of the subpopulations converges to 1, the relative size of this subpopulation converges to 1, and therefore the fraction of the whole population playing *A*, $z = r_A/r = \alpha x + y(1-\alpha)$ converges to 1. Which subpopulation prevails in this sense depends on the initial conditions, whether $x(0) > y(0)$ or $y(0) > x(0)$.

Let us note that the main result of our paper, as stated in the theorem, is also valid in the special case of equal replicator rates in each habitat, i.e. when $\kappa = 1$.

4. Conclusions

We discussed a dynamics of a single population of individuals playing a symmetric game. At any time, each individual resides in one of two disjoint different habitats. Differences between habitats (e.g. different ecology, fauna, flora, and feeding capacities) result in different speeds of replication. Players have knowledge of the expected payoffs from the strategy they are identified with in both habitats, and they choose the one with a higher expected payoff. The process of changing a habitat is referred to as migration. We assumed that the

coefficient of migration is the same in both subpopulations. More general case would give another (apart of the difference in replicator speeds) characterization of both habitats.

We showed that introduction of this mechanism of “attraction” by the habitat with a higher expected payoff in the standard replicator dynamics can help the whole population to reach the state in which in the long run most individuals play the efficient strategy.

More precisely, we proved that for a given rate of migration, if the fractions of individuals playing the efficient strategy in both habitats are not too close to each other, then the habitat with a higher fraction of such players overcomes the other one in the long run. The fraction of individuals playing the efficient strategy tends to unity in this habitat and consequently in the whole population. Alternatively, we may say that the bigger the rate of migration is, larger is the basin of attraction of the efficient equilibrium. In particular, we showed that for a large range of parameters of our dynamics, even if the initial conditions in both habitats are in the basin of attraction of the risk-dominant equilibrium (with respect to the standard replication dynamics without migration), in the long run most individuals play the efficient strategy.

The sizes of basins of attraction play an important role when deterministic dynamics is subject to stochastic perturbations due to mutations or players mistakes. The long-run behavior of noisy evolutionary processes can be described by stochastic stability of deterministic equilibria (Foster and Young, 1990). It was shown in many models that equilibria with larger basins of attraction (risk-dominant ones in the standard replicator dynamics) are stochastically stable (Harris and Fudenberg, 1992; Kandori et al., 1993); see also Robson and Vega-Redondo (1996), Vega-Redondo (1996), and Miękiś (2005) for models with randomly matched players. This is a consequence of the fact that the population needs more mutations to evolve from an equilibrium with a larger basin of attraction to the other equilibrium than in the case of the opposite transition. Therefore, for a low level of mutations, the population settles in the long run with a high probability in a state with a larger basin of attraction.

We plan to investigate in the future an appropriate stochastic version of our model. One has to carefully examine basins of attraction of both equilibria. The result of our paper suggests that the efficient equilibrium would be stochastically stable.
